## PREFACE.

FOR the past few years the writer of this book has given a course of lectures on the elementary theory of experimental electricity to a class of students at Trinity College, Cambridge. Experience, together with an occasional study of lecture note-books, has indicated that, to supplement the lectures, some definite and permanent statement is required—some book of reference, to which the students may turn for further elucidation of points not clear to them.

Thus the alternatives arose either of adapting the lectures to the lines of treatment of an existing book, or of writing a book which should correspond with the stage now reached in the evolution of teaching, which has extended over some ten years.

The great shift in the chief points of interest of experimental electricity, due to recent development in physical science, has changed the proportion of the various branches of the subject, and has put out of date many of the older standard text-books. To the phenomena of electrolysis, of conduction through gases, and of radio-activity, the physicist will now turn for knowledge newly acquired, for knowledge in the making, and for unsurveyed territory ready and waiting for the explorer. The writer has a firm belief in the advantage of giving to University students, even to those who confine themselves to an elementary study of their subjects, some insight into methods of research, together with some idea of recent results, and of unsolved problems ripe for

examination. In this way interest is aroused, and natural science is presented in its true light, as a living and growing branch of knowledge—imperfect indeed and incomplete as all human creations must be, but more fascinating by reason of its very faults and limitations, and the consequent possibility of unexpected and beneficent development.

In the opinion of the writer, education in physical science may proceed profitably on two lines only—either by keeping in close touch with the advance of pure knowledge or by instruction which brings into prominence the application of science to technical industry. Unless one or other of these courses be followed, the study of natural science by adult students is in danger of becoming dead and unprofitable both to teacher and learner. If the teacher be in touch both with the practical problems which arise in the technical application of his science and with the investigations into the unknown which are extending the bounds of pure knowledge, so much the better for himself and for his pupils; but, at least, let him try to keep in sight of one of them. Let him train his students as though all were to become engineers or investigators: those who end by becoming teachers will be all the better for the misunderstanding. The state of a science in which the instruction is only fit to train each succeeding generation to become the teacher of the next recalls the economic condition of the famous island where the inhabitants lived by taking in each other's washing.

Of those who approach physics from the experimental side, a large majority study simultaneously the kindred science of chemistry. From their point of view, it is an advantage that the branches of the subject of electricity now developing most rapidly are those in which the connexion with chemistry is most intimate. Here, again, the comparatively small space allotted to electrolysis, conduction through gases, and radio-activity in the usual text-

books is unsatisfactory. The unity of nature is best impressed on the observer by leading him to see the connexion between the different aspects in which, for the sake of convenience, our mental model of the world is presented. The fact that certain phenomena meet the student in his chemical work, is an argument, not for omitting their consideration from a course on physics, but for studying them with exceptional care, and for tracing their physical relations in the light of chemical knowledge.

In the following pages no attempt has been made to present a complete treatment of the science of electricity. The book is meant to be suggestive rather than exhaustive, to be an impressionist sketch rather than a finished picture. It aims at bringing into prominence those features which strike the writer as essential, without wearying the reader with a mass of unnecessary detail. An educational work is better too short than too long; better when in some points leaving curiosity unsatisfied than when attaining an ill-digested completeness. The object of the present undertaking has been to implant a thorough and clear knowledge of those physical principles necessary for an appreciation of the newer parts of the subject. All digressions, though interesting perhaps to the mathematician or experimenter, have been curtailed. The book is meant as an organic structure, each part of which has a definite and inevitable relation with the whole, each section its bearing on the plot of the story. To some extent, even a scientific text-book perforce must be a piece of literature and a work of art. Whether that necessity be welcomed or not, nothing is lost by keeping it clearly in mind.

The writer wishes to thank his wife, whose help, as always, has been freely given. Mr Norman Campbell, Fellow of Trinity College, has read the proof-sheets of the book. Mr G. F. C. Searle, of Peterhouse, has given his advice on several points; while the influence and inspiration of Professor J. J. Thomson will be

evident throughout the work. In places the treatment is based on the writer's treatise on the *Theory of Solution*, and in others on his book on *The Recent Development of Physical Science*. Acknowledgment of this fact is due to the publishers of those two works, the Cambridge University Press, and Mr John Murray respectively.

## CHAPTER I.

### GENERAL PRINCIPLES OF ELECTROSTATICS.

Early History. Franklin's work. Electric induction. Fluid theories of electricity. Variation of electric forces with distance. Quantity of electricity. Electric force or electric intensity. Electric potential. Electric capacity. Distribution of electricity on the surface of conductors. Specific inductive capacity or dielectric constant.

1. It was known to many in ancient Greece and Rome that  
Early History.      amber and some other substances possessed, when rubbed, the power of attracting light bodies. Moreover, the shocks received on touching the fish called the torpedo were described by Pliny, and had been used to cure gout; though it is safe to surmise that no connexion was suspected between these apparently unrelated phenomena, or between either of them and the thunderbolts of Jove. Lucretius, who commented on the latter phenomena, hesitated to ascribe them to Divine interposition, observing that temples, even of Jove, far from being exempt, were especially liable to the visitation.

Though references to these facts, and speculations as to their nature, are scattered throughout the writings of the Middle Ages, no real advance on the knowledge of the ancients was made till Dr Gilbert (1540—1603) repeated the experiments with a view to finding some explanation.

William Gilbert, a native of Colchester, Fellow of St John's College, Cambridge, and sometime President of the College of Physicians, was one of the earliest and most distinguished of our English men of science—a man whose work Galileo himself thought enviably great. He was appointed Court physician to Queen

Elizabeth and James I., and a pension was settled on him to set him free to continue his researches in Physics and Chemistry.

It is to Gilbert that we owe the name electricity, which he derived from the Greek word *ἤλεκτρον*, amber. By investigating the forces on a light metallic needle, balanced on a point, he extended the list of electric bodies, and found also that many substances, including metals and natural magnets, showed no attractive forces when rubbed. He noticed that dry weather with north or east wind was the most favourable atmospheric condition for exhibiting electric phenomena—an observation liable to misconception till the difference between conductor and insulator was understood.

Gilbert's work was followed up by Robert Boyle (1627—1691), the famous natural philosopher who was once described as "father of Chemistry, and uncle of the Earl of Cork." Boyle was one of the founders of the Royal Society when it met privately in Oxford, and became a member of the Council after the Society was incorporated by Charles II. in 1663. He worked frequently at the new science of electricity, and added several substances to Gilbert's list of electrics. He left a detailed account of his researches under the title of *Experiments on the Origin of Electricity*.

The first to note that light and sound accompanied strong electric excitation was Otto von Guericke (1602—1686) of Magdeburg, who mounted a sulphur ball on a revolving axis and rubbed it with the hand. With this primitive electric machine he repeated the earlier experiments on a larger scale, and made the important discovery that, when once a light body had touched an electrified substance, it was thereupon repelled till it had touched some other object, when attraction again supervened.

In 1729 Stephen Gray discovered the electric properties of conductors and insulators, and, in conjunction with Wheeler, conveyed the electricity from a piece of rubbed glass over a distance of 886 feet, through a packthread suspended by silk loops. He found that the experiment failed if loops of hemp or wire were used, and also noted the conducting power of fluids and of the human body. Desaguliers added to these results the observation that conductors appeared not to be electrified by friction, a conclusion he would not have reached had he supported the conductors

on insulating supports. Desaguliers' observation led to conductors being called non-electrics, a name they kept for many years.

About the same time Dufay, working in France, showed that two bodies electrified by contact with rubbed glass, or two bodies electrified from resin, repelled each other, while one of the first named would attract one of the latter. He was thus led to recognise two kinds of electricity—vitreous and resinous. Gray, who repeated his experiments, had already noted that the body used as rubber acquired as intense an electrification as did the object rubbed; and also, supported by some of his fellow-workers, suggested the identity of the electric fire with lightning.

The electric machine was now improved and increased in power, mainly by German and Dutch philosophers. A prime conductor, to collect the electric charge as formed, was added, and sparks of sufficient intensity to ignite spirits of wine were obtained.

The condenser originated in consequence of observations on the leakage of charge. This leakage, which always took place in open air and especially in damp air, gave rise to the notion that the charge might be preserved if surrounded by a non-conductor. The condenser seems to have been invented by more than one person. From Muschenbroech of Leyden it took its name of the Leyden jar, and by him its properties were discovered in the attempt to electrify water in a glass bottle held in the hand. Dr Bevis suggested coating the outside of the jar with a metallic covering, and such a jar filled with water seems to have been used by Franklin and others. When both inside and outside had been coated with tin-foil, at the suggestion of Sir William Watson, the Leyden jar was complete. (Fig. 1.)

Fig. 1.

Watson directed a series of experiments for the Royal Society with a view to measuring the velocity of electricity. The velocity was of course much too great to be answerable to the experimental appliances of the time, and, even through more than 12,000 feet

of wire, propagation was pronounced to be instantaneous. With reference to these experiments, Watson remarks "that when the observers have been shocked at the end of two miles of wire, we infer that the electrical circuit is four miles, viz. two miles of wire and the space of two miles of the non-electric (conducting) matter between the observers, whether it be water, earth, or both." This seems to be the first occasion when the earth was used and recognised as a return circuit.

2. Watson suggested that the two kinds of electrification might represent the excess and defect in a single kind of electricity, and this "single fluid theory," with its positive and negative charges, was elaborated and made more definite by Dr Benjamin Franklin of Philadelphia (1706–1790), journalist, philosopher, and statesman. Franklin showed that the two coatings of a Leyden jar were oppositely electrified, and that, in the terms of the one fluid theory, as much electricity escaped from the outer coating as entered the inner coating. "The phial will not suffer what is called a charging unless as much fire can go out of it one way as is thrown in by another. A phial cannot be charged standing on wax or glass, or hanging on the prime conductor, unless a communication be form'd between its coating and the floor.

"When a bottle is charged in the common way its *inside* and *outside* surfaces stand ready, the one to give fire by the hook, the other to receive it by the coating; the one is full and ready to throw out, the other empty and extremely hungry; yet as the first will not *give out*, unless the other can at the same instant *receive in*, so neither will the latter receive in, unless the first can at the same instant give out. When both can be done at once 'tis done with inconceivable quickness and violence."

The ideas prevalent at that time regarded the electricity stored in the jar as analogous to a liquid stored in a bottle; but Franklin, setting himself to determine the essential features of the jar, found that similar effects could be obtained by placing two sheets of lead, one on each side of a plane sheet of glass. By gilding the glass in front of a picture of the King, Franklin was able, by means of a violent electric shock, to frustrate the efforts of

“the conspirators” who endeavoured to take off a little moveable gilt crown from the King’s head. In after years he may have remembered this playful experiment when, his efforts to prevent a quarrel having failed, Franklin, both in his own land and as ambassador to France, did much to remove from the King’s crown the bright jewel of the American colonies.

Franklin found that a sharp point near an electrified body caused it to lose its charge, and noticed the glow which such a point presents in a darkened room. From experiments like these he reached the conception of an electric atmosphere surrounding charged bodies, and concluded that the charge resided on the surface. The Leyden jar, moreover, showed phenomena which indicated that the charge resided, not on the coatings, but in the glass itself.

“The whole force of the bottle, and power of giving a shock, is in the GLASS ITSELF; the non-electrics in contact with the two surfaces serving only to *give* and *receive* to and from the several parts of the glass; that is, to give on one side, and take away from the other.

“This was discovered here in the following manner. Purposing to analyse the electrified bottle, in order to find wherein its strength lay, we placed it on glass, and drew out the cork and wire which for that purpose had been loosely put in. Then taking the bottle in one hand, and bringing a finger of the other near its mouth, a strong spark came from the water, and the shock was as violent as if the wire had remained in it, which showed that the force did not lie in the wire. Then to find if it resided in the water, being crowded into and condensed in it, as confin’d by the glass, which had been our former opinion, we electrified the bottle again, and placing it on glass, drew out the wire and cork as before; then taking up the bottle we decanted all its water into an empty bottle, which likewise stood on glass; and taking up that other bottle, we expected if the force resided in the water to find a shock from it; but there was none. We judged then that it must either be lost in decanting or remain in the first bottle. The latter we found to be true: for that bottle on trial gave the shock, though filled up as it stood with fresh unelectrified water from a teapot. To find, then, whether glass had this property

merely as glass, or whether the form contributed anything to it, we took a pane of sash glass and laying it on the stand placed a plate of lead on its upper surface; then electrified that plate, and bringing a finger to it, there was a spark and shock. We then took two plates of lead of equal dimensions, but less than the glass by two inches every way, and electrified the glass between them, by electrifying the uppermost lead; then separated the glass from the lead, in doing which what little fire might be in the lead was taken out and the glass being touched in the electrified parts with a finger, afforded only very small pricking sparks, but a great number of them might be taken from different places. Then dexterously placing it again between the leaden plates, and completing a circle between the two surfaces, a violent shock ensued.—Which demonstrated the power to reside in glass as glass, and that the non-electrics in contact served only, like the armature of a loadstone, to unite the force of the several parts and bring them at once to any point desired: it being a property of a non-electric that the whole body instantly receives or gives what electrical fire is given or taken from any one of its parts.”

In the last sentence Franklin clearly shows that he understood the essential nature of the then-called non-electrics as conductors of electricity. The experiment with the Leyden jar makes plain the paramount part played in electrical phenomena by the non-conductor, or, as it was then termed, the electric *per se*.

This experiment is of fundamental importance, for the modern theory of electricity, as we shall see, regards the dielectric as the essential seat of electrical manifestations. On this foundation Faraday and Maxwell laid the corner-stones of electrical science.

As soon as the spark and noise of an electric discharge were noticed, their resemblance to lightning and thunder was recognised, and the identity in nature of the two phenomena suspected. The problem of the establishment of this identity seems to have possessed a fascination for the mind of Franklin, and many of his later letters are filled with the description of experiments repeating on a small scale, with the charges of Leyden jars, the effects of lightning in fusing metals, rending materials, &c. The discharging action of points suggested to Franklin the idea of the lightning-conductor.

“May not the knowledge of this power of points be of use to mankind, in preserving houses, churches, ships, &c. from the stroke of lightning, by directing us to fix on the highest parts of those edifices upright rods of iron made sharp as a needle, and gilt to prevent rusting, and from the foot of those rods a wire down the outside of the building into the ground, or down round one of the shrouds of a ship, and down her side till it reaches the water? Would not these pointed rods probably draw the electrical fire silently out of a cloud, before it came near enough to strike, and thereby secure us from that most sudden and terrible mischief?”

Franklin then goes on to suggest that in order “to determine the question whether the clouds that contain lightning are electrified or not” an iron rod should be erected on some high tower or steeple. When thunder-clouds passed, sparks might be drawn from the lower end of the rod.

The letters containing this suggestion led to its adoption in France, England, and other countries, with complete success—a success, too complete indeed in the case of Professor Riehm of St Petersburg, who was killed by a shock from an iron rod erected on his house. Meanwhile Franklin himself had safely carried out a similar experiment by means of a kite.

“To the top of the upright stick of the kite is to be fixed a very sharp pointed wire, rising a foot or more above the wood. To the end of the twine, next the hand, is to be tied a silk ribbon, and where the silk and twine join a key may be fastened. This kite is to be raised when a thunder-gust appears to be coming on, and the person who holds the string must stand within a door or window, or under some cover, so that the silk ribbon may not be wet; and care must be taken that the twine does not touch the frame of the door or window. As soon as any of the thunder-clouds come over the kite the pointed wire will draw the electric fire from them, and the kite, with all the twine, will be electrified, and the loose filaments of the twine will stand out every way and be attracted by an approaching finger. And when the rain has wet the kite and twine, so that it can conduct the electric fire freely, you will find it stream out plentifully from the key on the approach of your knuckle. At this key the phial may be charged; and from electric fire thus obtained spirits may be kindled, and all

the other electric experiments be performed, which are usually done by the help of a rubbed glass globe or tube, and thereby the sameness of the electric matter with that of lightning completely demonstrated."

During the eighteenth century, many experiments were made on the electrification produced by heating certain minerals and crystals, such as tourmaline; and attention was drawn once more to the benumbing power of shocks given by the torpedo and certain other fish. Their electrical organs were examined, and the shocks they inflict were ascribed definitely to electrical manifestations.

3. While Franklin pursued his researches in America, an English philosopher and schoolmaster, John Canton (1718—1772), born at Stroud in Gloucestershire, was working on parallel lines in London. In 1750 he received a medal from the Royal Society in recognition of his improvements in artificial magnets, and in 1752 he was the first in England to verify his friend Franklin's demonstration of the identity of lightning and electricity.

But perhaps the greatest of Canton's discoveries was the process of electrification by induction, which he explained in terms of the theory of electrical atmospheres. If an insulated conductor, let us say of a cylindrical form, is placed in the neighbourhood of a charged body, the nearer end of the cylinder acquires a charge of the opposite sign, and the farther end a charge of the same sign as that on the body. The charges may be demonstrated by fitting the cylinder with vertical metal stands, from which hang linen threads carrying pith balls. An electric charge repels the balls from the stands (Fig. 2). If the cylinder, still insulated, be removed from the neighbourhood of the original charge, the charges on the cylinder neutralize each other. If, however, while

Fig. 2.

under the influence of the electrified body, the cylinder be touched with the finger or otherwise connected with the earth, the charge of the same name as that of the inducing body escapes, and the

cylinder retains the charge of the opposite name. As long as the electrified body is near, this induced charge remains fixed or bound: it will not escape even along a conductor. When, however, the electrified body and the cylinder are separated, the induced charge becomes free; the cylinder acts as an ordinary charged system—it will share its charge with any other insulated conductor in contact with it, and lose its charge to earth if a passage be opened. These phenomena admit of an obvious explanation in terms of the attraction between unlike charges and the repulsion between those of the same name, the original uncharged cylinder being imagined to contain equal and opposite quantities of “vitreous and resinous” or of “positive and negative” electricity.

Electrostatic induction gives us the best means of obtaining a continuous series of electric charges, and on this principle all modern electric machines are based.

The simplest influence machine is the electrophorus of Volta, invented in 1775. It consists of a plate of resin or vulcanite which is electrified by rubbing it with cats’ fur. A brass plate, held on an insulating handle, is then placed upon it, and touched with the finger. The negatively electrified vulcanite induces a positive charge on the lower surface of the brass plate and repels the corresponding negative charge to earth. The finger is then

Fig. 3.

Fig. 4.

removed, leaving the brass plate insulated with its positive charge. If it be now raised from the cake of vulcanite, work is done against the electric forces, the positive charge is set free, and can be

communicated to other conductors. The energy of the electric charge obviously is derived from the work of electric separation performed in raising the charged plate from the oppositely electrified vulcanite; as long as the two charges are in close proximity, they are unavailable, and possess no energy. The charge on the vulcanite is not sensibly affected by the working of the instrument, since the brass plate touches it at a few points only. Thus the brass plate can be replaced, and the process repeated till the original charge is lost by leakage. A continuous series of charges is obtained at the expense of manual labour.

Fig. 5.

Similar principles are applied in the powerful influence machine invented by Wimshurst and now used extensively in physical laboratories (Fig. 5). Two shellac-coated glass plates are made to revolve in opposite directions by means of a hand-wheel or motor. Sectors of thin brass or tin-foil are fixed to the outer surfaces of the plates as indicated in the figure. These sectors are touched as they revolve by wire brushes on the ends of two uninsulated diagonal conductors. To start the machine, a charged ebonite rod is held opposite one of these brushes. The negative charge on the rod, acting through the two glass plates, induces a positive charge on the sector, the corresponding negative charge escaping through

the brush. The positively charged sector passes on, till it comes opposite the brush on the other side of the machine. Here it induces a negative charge on one of the sectors of the other plate then in contact with the brush, and finally gives up its charge to one of the collecting combs which are connected with the terminals of the machine. Thus, each charged sector acts as an inducing agent for sectors on the opposite plate before rendering up its charge. Once started, the machine increases its own charges, till leakage or discharge between the terminals prevents further accumulation. Large Wimshurst machines, with several pairs of plates, are now often worked by electric motors, and give a constant stream of opposite charges of very great intensity.

4. As we have seen, the phenomena of electricity known in the middle of the eighteenth century were explained by the single fluid theory of Watson and Franklin. Fluid theories of electricity. An alternative explanation was, however, suggested by other physicists. According to this second view, the two kinds of electrification were to be explained as the manifestation of two imponderable fluids, co-existent but with opposite properties, which neutralized each other. But the age was not ready for such fundamental and detailed theories of electricity; in fact, even now we are not in a position to accept finally any theory as to its ultimate nature, and we still do not certainly know whether electricity is two or one. Nevertheless, the single and double fluid theories were most useful working models, and played the true part of scientific hypotheses in enabling observers to describe and coordinate the phenomena, and to find new and profitable fields of research.

At the period we are now considering, the knowledge already acquired might be summarized by saying that, in unelectrified bodies, equal quantities of the opposite electric fluids existed, and that, by the friction of certain substances, a separation between the fluids might be effected. The fluids passed easily through the interstices of conductors or non-electrics, substances which, when held in the hand, could not be electrified by friction, but only moved with great difficulty through electrics or non-conductors. Each electric fluid tended to spread over the surface of any

conductor; the different portions of the fluid seemingly exerted a repulsive force on each other. Moreover, two bodies similarly electrified repelled each other. On the other hand, opposite electricities on the same conductor tended to approach and neutralize each other, while two bodies oppositely electrified were subject to a force of attraction. Electric charges at rest were found only on the surface of conductors, but in motion they used the whole substance of the conductor and not merely its surface. Those doubtful on this point might, according to Franklin, be convinced by the passage of an electric shock through the substance of their bodies.

The properties of condensers or Leyden jars were explained by the attraction of the opposite charges collected or condensed on their coatings; though, as we have seen, Franklin had already shown that the glass itself played the more essential part in the process.

As soon as we attempt to deal with the fluids of the two-fluid theory as other than mathematical abstractions, the difficulty of the conception becomes manifest. We have to suppose that the mixture of two fluids in equal proportions gives us something so devoid of properties that it cannot be detected. The one-fluid theory, as developed by Franklin, avoids this difficulty. In his view, portions of the single positive fluid attract ordinary matter and repel other portions of electricity. Unelectrified matter is supposed to be associated with so much of the electric fluid that the attraction of external electricity for the matter is just balanced by the repulsion for the normal charge associated with it. Excess of the fluid beyond the normal charge means positive electrification, defect means negative electrification. There is much in Franklin's theory which resembles modern conceptions of electrical phenomena, though there is now reason to suppose that what is called negative electrification should have been given the positive sign.

5. At this stage of the science, the most important phenomena were the attractions and repulsions between electrified bodies, and the investigation of these forces became the immediate object of experimenters. The Newtonian law of gravitation must have suggested the possibility that,

Variation of  
electric forces  
with distance.

in electric phenomena also, we are dealing with forces which vary inversely as the square of the distance. It was shown by *Æpinus*, a German philosopher who lived from 1724 to 1806, that the force diminished as the distance increased, but a satisfactory demonstration of the truth of the inverse square law was first published by Robison and soon after by Charles Augustin Coulomb of Montpellier (1736—1806), a distinguished military engineer in the service of France, and a member of the Académie des Sciences. Coulomb's researches were carried on by means of an instrument of his own invention, known as the torsion balance. Nevertheless, as we shall see presently, a more accurate method than that of Coulomb had been worked out and used previously by Cavendish, though with characteristic reticence he had not thought fit to give his discovery to the world.

The original idea of measuring small forces by balancing them against the torsion of a wire seems to have been due to the Rev. John Michell, whose method was applied by Cavendish in 1797 to determine the gravitational attraction between balls of lead. Coulomb, probably unaware of Michell's suggestion, investigated experimentally the couple required to twist a wire through a given angle, and found that it varied as the angle and as the fourth power of the diameter of the wire. He then constructed a balance, such as is illustrated in Fig. 6, and used it to investigate electric forces.

Fig. 6.

To the centre of the top of a cylindrical glass case a vertical glass tube is fixed. At the upper end of the tube is fitted a graduated torsion head from which hangs a fine silver wire. The wire carries a thin straw, covered with sealing-wax, with a small pith ball at one end and a vertical disc of oiled paper (not shown in the figure) at the other. The disc acts as a damper of

the oscillations of the bar, and as a pointer by means of which the position of the bar is ascertained on a graduated circle surrounding the middle of the glass case. A second hole, towards the side of the top of the case, admits a vertical rod of shellac, suspended by a clip and carrying a second conducting ball, which is thus placed in a fixed position within the case, such that the centre of the ball lies between the zero of the graduations on the case and the lower end of the hanging wire. The fixed ball being removed, the torsion head is adjusted till the suspended ball lies with its centre at the same point. The fixed ball is then reinserted, and, when the moveable ball has come to rest in contact with it, both are electrified by means of a small metal ball carried on an insulating handle. The moveable ball is repelled, and takes up a position of equilibrium under the electric repulsion and the force of torsion. Its position on the graduated circle is then noted. The torsion head is now turned round so as to force the moveable ball nearer to the other, and a note is made of the angle through which the torsion head is turned and the new position of equilibrium of the suspended arm.

Knowing the two angular positions of equilibrium, it is easy to calculate in each case the distances between the balls. The angles of torsion are determined by observing the graduations on the torsion head and on the glass case. The torsional couple being proportional to the angle of twist in the wire, a relation between electric force and distance is obtained. If the balls are small compared with the distance between them, the relation is found to be approximately that of the inverse square.

As a simple example of the method, let us imagine that, after the moveable ball has been repelled through an angle  $\alpha$ , the torsion head is turned through an angle  $\beta$  till the original distance  $d$  between the balls is halved. The angular deviation of the moveable arm is now less than  $\alpha$ , let us suppose  $\gamma$ , and the total twist in the wire is  $\gamma + \beta$  instead of  $\alpha$ , as at first. It will now be found that  $\gamma + \beta$  is approximately four times  $\alpha$ , showing that halving the distance has increased the force in the ratio of 1 to 4. In a similar

Fig. 7.

manner, diminishing the distance to one-third will be found to increase the torsional and electric forces in the ratio of 1 to 9.

While such experiments serve to show that the law of inverse squares is not far from the truth, they are not susceptible of any great accuracy. The law, as we shall see later, is only exact if the dimensions of the charged bodies are infinitely small compared with the distance between them, or if the bodies consist of spheres uniformly electrified. Now, although the bodies in Coulomb's apparatus are spheres, they are not uniformly electrified, for the repulsive action between the charges concentrates them on the farthest parts of the spheres. Besides this difficulty, the unavoidable leakage of charge during the course of the measurements renders the experiment uncertain in result. The torsion balance, in less experienced hands than those of Coulomb, is very far from being an instrument of precision.

Fortunately we are not dependent on the torsion balance for an exact verification of the law of inverse squares, and, as already stated, another method had been devised and carried out for his own satisfaction by Henry Cavendish some years before the publication of Coulomb's results. Cavendish discovered many things which are now associated with the names of other men, for it was only when his unpublished manuscripts, belonging to the Duke of Devonshire, were edited by Clerk Maxwell in 1879, that the world understood to what an extent he had anticipated the conclusions of more recent times. As Maxwell says, "Cavendish cared more for investigation than publication. He would undertake the most laborious researches in order to clear up a difficulty which no one but himself could appreciate, or was even aware of, and we cannot doubt that the result of his enquiries, when successful, gave him a certain degree of satisfaction. But it did not excite in him that desire to communicate the discovery to others which, in the case of ordinary men of science, generally ensures the publication of their results. How completely these researches of Cavendish remained unknown.....is shown by the external history of electricity." In the present age of publicity we may perhaps overrate the eccentricity of Cavendish's character, but, even in his own more leisurely days, that eccentricity seems to have arrested attention.

Cavendish's method of examining the law of force depends on

the experimental proof that there is no electric force within a charged sphere. Newton in his *Principia* had demonstrated that, on the assumption of an inverse square law, the gravitational force would vanish within a uniform spherical shell of gravitating matter. It is easy to transfer the proof to the case of uniform electrification, which is mathematically similar.

Let us consider the resultant force at the point  $P$  within the sphere. With  $P$  as common apex, draw two small equal-angled cones with their axes in the same straight line on opposite sides of  $P$ . The bases of these two small cones being very small, we may take the area  $A$  of one base to be at a constant distance from  $P$ , and to act as an electrified particle. By hypothesis, therefore, its charge will act at  $P$  with a force proportional to  $1/(PA)^2$ ; similarly the charge on  $a$  will act with a force proportional to  $1/(Pa)^2$ . But, the sphere being uniformly electrified, the charges on these areas  $A$  and  $a$  will be proportional to the areas. Now, the bases being equally inclined to the axes of the cones, they will possess areas directly proportional to the squares  $(PA)^2$  and  $(Pa)^2$ . Thus, the forces at  $P$  due to the charges on  $A$  and  $a$  will increase with distance as much as they diminish, and will be the same as though the charges were at the same distance from  $P$ , when obviously the forces they exert are equal and opposite. The force at  $P$  due to the two elementary cones, then, vanishes; and by dividing the whole surface of the sphere into elementary areas by similar pairs of cones, it is clear that the force due to each pair of cones must vanish also, so that there is no resultant force.

We have now shown that the assumption of the law of inverse squares leads to the disappearance of electric force within a uniformly charged sphere. It remains to prove that no other law is consistent with this result. Through a point  $P$ , inside a sphere with centre  $O$  (Fig. 9), draw a plane at right angles to  $OP$ . If the charge on the part of the sphere above this plane produces an

Fig. 8.

Fig. 9.

attraction in the direction  $OP$ , that below the plane will act in the direction  $PO$ . When the law is that of the inverse square, these two forces balance each other. If the force decrease with increase of distance at some rate higher than the square, the force due to the electrification of the larger area below the plane will fall off at a rate too fast to be compensated by the greater effect of the larger area. The resultant force will therefore act in the direction  $OP$  towards the smaller area. On the other hand, if the force diminish less fast than the square of the distance increases, the greater distance from  $P$  of the larger area will be overcome by the effect of the larger charge, and there will be a resultant force in the reverse direction.

It follows, therefore, that no power of the distance other than the inverse square is consistent with no electric force within the uniformly charged sphere. Maxwell pointed out that the experimental fact, which was known to Cavendish, that the distribution of electricity was similar on similar figures, irrespective of size, shows that the law of force must involve some power of the distance and no other mathematical function. If, then, it can be shown experimentally that there is no electric force within a uniformly charged sphere, it must follow that the inverse square is the only possible law of force. This result was first given in a general form by Laplace, though, as we have stated, owing to the known experimental properties of similar bodies, Cavendish's assumption of some power of the distance does not sacrifice the generality of his proof.

Whenever an electric force acts on a conductor, as we have seen above, electric separation occurs, and parts of the conductor become electrified differently to other parts. If we find that, within a charged conductor, no separation of electricity occurs, it shows that no electric force exists.

To examine this point, Cavendish says, "I took a globe 12.1 inches in diameter, and suspended it by a solid stick of glass run through the middle of it as an axis, and covered with sealing-wax to make it a more perfect non-conductor of electricity<sup>1</sup>. I then inclosed this globe between two hollow pasteboard hemi-

<sup>1</sup> Glass is hygroscopic, and in damp weather becomes covered with a conducting film of moisture.

spheres, 13·3 inches in diameter...in such manner that there could hardly be less than  $\frac{4}{10}$  of an inch distance between the globe and the inner surface of the hemispheres in any part, the two hemispheres being applied to each other so as to form a complete sphere, and the edges made to fit as close as possible, notches being cut in each of them so as to form holes for the stick of glass to pass through.

“By this means I had an inner globe included within a hollow globe in such a manner that there was no communication by which the electricity could pass from one to the other.

“I then made a communication between them by a piece of wire run through one of the hemispheres and touching the inner globe, a piece of silk string being fastened to the end of the wire by which I could draw it out at pleasure.

“Having done this I electrified the hemispheres by means of a wire communicating with the positive side of a Leyden phial, and then, having withdrawn this wire, immediately drew out the wire which made a communication between the inner globe and the outer one, which, as it was drawn away by a silk string, could not discharge the electricity either of the globe or hemispheres. I then instantly separated the two hemispheres, taking care in doing it that they should not touch the inner globe, and applied a pair of small pith balls, suspended by fine linen threads, to the inner globe, to see whether it was at all over or undercharged<sup>1</sup>.

“The result was that though the experiment was repeated several times I could never perceive the pith balls to separate or show any signs of electricity.....

“Hence it follows that the electric attraction and repulsion must be inversely as the square of the distance, and that when a globe is positively electrified the redundant fluid in it is lodged entirely on its surface.....

“In order to form some estimate how much the law of the electric attraction and repulsion may differ from that of the inverse duplicate ratio of the distances without its having been perceived in this experiment” Cavendish tested the sensitiveness of his apparatus by communicating to the inner sphere an amount of electricity which was just appreciable with the pith balls, and was

<sup>1</sup> *i.e.* positively or negatively electrified.

equal to a known fraction of that communicated to the outer sphere in the experiment described. "We may conclude that the electric attraction and repulsion must be inversely as some power of the distance between that of the  $2 + \frac{1}{50}$ th and that of the  $2 - \frac{1}{50}$ th, and there is no reason to think that it differs at all from the inverse duplicate ratio."

A similar experiment was carried out, using a hollow rectangular box instead of the folding hemispheres, with a similar result. Whatever the form of the conductor, as long as it is completely closed, there is no electric force within it.

Truly this research is no less remarkable as a model of scientific method, than for the importance of the results obtained.

The pair of pith balls used by Cavendish do not constitute a sensitive electroscope. A more delicate instrument, invented by Bennet, consists of two gold-leaves suspended from a wire placed within a glass jar. When electrified, the leaves repel each other and diverge at an angle which roughly indicates the intensity of electrification. In recent years the gold-leaf electroscope has become an instrument of accurate research, and is employed for

Fig. 10.

Fig. 11.

measuring the electrical conductivity of air and other gases under the influence of Röntgen rays, radio-active substances, etc. In its modern form, a single strip of gold-leaf *C* is attached to a brass plate *D* (Fig. 11), from which the leaf is repelled when electrified.

With a gold-leaf electroscope, it has been possible to obtain a

much more exact confirmation of the law of inverse square than was effected by Cavendish. Faraday, for instance, constructed a wooden cube covered with tin-foil, large enough to contain himself and his electroscopic instruments. The cube was supported on insulating feet, and intensely electrified. Even when brush and spark discharges were darting from the outside, no electrification could be detected within.

Using Lord Kelvin's quadrant electrometer (§ 20) Maxwell, about the year 1870, repeated Cavendish's experiment, and came to the conclusion that the power of the distance involved in the law of force cannot differ from 2 by more than the  $1/21600$ th part.

The fact that the charge on a system resides on the outside only may be demonstrated roughly in many ways, one of which is a modification of Cavendish's experiment with the separable hemispheres (Fig. 12).

Fig. 12.

Besides its chief interest as a means of verifying the law of inverse square, the fact

that there is no electric force inside a closed conductor of any form, carrying any distribution of electricity, shows that such a conductor serves to screen points within it from electrostatic disturbances due to outside electrification. For effective screening, it is not necessary to have a continuous conductor. A cover of wire-gauze, as shown in Fig. 10, or even strips of tin-foil pasted on a glass shade, are usually sufficient protection to electric instruments placed within. The indications of such instruments are not affected by charges without the screen.

6. In order to acquire the power of measuring definitely any

Quantity of  
electricity.

physical quantity, it is necessary to find some satisfactory method of defining the unit of the quantity, and to show that, in certain conditions at all events, the quantity

we are dealing with does not arbitrarily increase or decrease—that, in certain circumstances, it is a conservative quantity. Thus, mass and energy are quantities. Units can be devised, and two masses or two quantities of energy can be added together so that the joint mass or energy is the sum of the parts. The temperature of a mixture of two volumes of water, on the other hand, is not the sum of those of the two before junction. In this sense, temperature is not a physical quantity.

A knowledge of the laws of electric attraction and repulsion, and of their variation with the distance, enables us to define a convenient unit for quantity of electricity. In terms of this unit, it is found that all known phenomena are consistent with the supposition that electricity may be treated as a real physical quantity. Two quantities of electricity of the same kind can be given to the same insulated conductor, and, as measured by its external electric forces, that conductor, allowing for the loss by leakage, will then possess a charge represented by the sum of the two charges communicated. Should the two charges be of opposite kinds, the same statement describes the facts if by the sum, the algebraic sum be understood.

The use of the term “quantity of electricity” is justified and the phenomena of induction are well illustrated by some experiments of Faraday, who used a pewter ice-pail to represent a nearly closed conductor. The ice-pail was placed on an insulating stand and connected with an electroscope by means of a wire. A brass ball, suspended by a long thread of white silk, was electrified, and gradually lowered into the pail. As it approached, the leaves of the electroscope diverged, and the divergence increased till the ball was well inside the vessel, some few inches below the top. The divergence of the leaves then became constant, however the

Fig. 13.

ball was moved about within the pail. If its charge were shared with another ball, no change appeared in the indications of the electroscope. Finally, if the ball touched the inside surface of the vessel, again the divergence of the gold-leaves was unaffected. The whole of the charge on the ball now had passed to the outside of the surrounding vessel, and this was verified by removing the ball, when the leaves maintained their deflection, and the ball was shown to be unelectrified.

Two chief conclusions may be drawn from these facts :

(1) The deflection of the electroscope depends on something which remains constant however the charged ball be moved, when that ball is once fairly within the vessel, and however the charge be distributed ; we may call this something a quantity of electricity, the quantity remaining constant, and not depending on the nature, position, or size of the charged body.

(2) Let us then accept the idea of a quantity of electricity, and the fact that, on contact with the inside, the whole of the charge on the ball passes to the outside. It follows from the constancy of the deflection on contact that the quantity of electricity distributed on the inside of the vessel at first, owing to induction, must be equal and opposite to the charge on the ball, since, when they coalesce, they leave the charge on the outside unaffected. Touching the inside of the vessel with the ball only leaves the deflection unaltered if the charge is effectively surrounded on all sides by the vessel. Thus, for the induced charge to be equal as well as opposite to the inducing charge, the outside conductor must completely surround the charged body.

In the light of our knowledge of the laws of electric force, the electrostatic unit of quantity of electricity may be defined conveniently as that quantity which, when placed on a small particle at unit distance from a similarly electrified particle, repels it with unit force when the two particles are separated by air. In the system of units usually adopted, the unit of distance is the centimetre, and the unit of force the dyne. Now, it can be shown experimentally, by means of the torsion balance for instance, that two such units in conjunction produce a doubled force on the

repelled unit—the electric forces vary as the product of the quantities of electricity and inversely as the square of the distance between them. Writing  $e_1$  and  $e_2$  for the two quantities of electricity, and  $r$  for the distance, we have

$$F = \frac{e_1 e_2}{r^2},$$

for the force between them when separated by air. We shall see presently that, in the general case, when any insulating medium lies between the charges, another factor must enter into this expression.

7. In the equation given above,  $F$  denotes the mechanical force acting between two similarly electrified particles.

Electric force  
or electric  
intensity.

It must not be confused with another quantity, of different physical dimensions, which is called the electric force or the electric intensity. Let us suppose that, in some way or other, an electric field is set up. An electrified body placed in that field is subject to forces, but the amount of force it suffers depends on the charge on the body. It is convenient to have some quantity to express the state of the field independently of any charge used to explore it. The electric intensity at any point of the field is defined as the mechanical force which would be exerted on a particle, charged with unit quantity of positive electricity and placed at the point. If we denote the electric intensity by  $f$ , the mechanical force on a body carrying a charge  $e$  is

$$F = fe,$$

so that the dimensions of  $f$  are those of mechanical force divided by those of quantity of electricity.

Electric intensity, like mechanical force, is a vector quantity—it involves the idea of direction. A line drawn through an electric field so as always to coincide in direction with the electric intensity is known as a line of force. In another place we shall have much to say about lines of force.

8. The early experimenters soon found that it was impossible

Electric  
potential.

to electrify a system without limit. As the process continued, leakage increased, and eventually luminous discharges appeared, which carried away the charge as fast as it

was imparted to the system. With a given source of electricity, this stage was reached sooner with small systems than with large ones. Hence arose the ideas of quantity of electricity, of the electric capacity of the receiving system, and of the degree of electrification, or what we now term the potential.

Cavendish seems to have been distinguished from his predecessors and contemporaries by a clear grasp of the meaning of the phrase "degree of electrification" and by an exact definition of it. In terms of his fluid theory, he boldly gave it a physical meaning as the pressure of the fluid. The relative degrees of electrification determine in which direction electricity will pass when two bodies are connected by means of a conductor, and, when equilibrium has been attained, the potential of the bodies must be the same: all parts of a conducting system must be at the same potential when its charge is at rest. In this sense electric potential is analogous to temperature in heat, or to pressure in hydrodynamics.

The difference of electric potential between two points may be defined as the work done against the electric forces in bringing one positive unit of electricity from one point to the other, the movement of the unit charge being supposed to produce no appreciable change in the potential. The electric potential of any single point in space then is best defined as the amount of work it is necessary to do against the electric forces in bringing up to the point a particle charged with one unit of positive electricity from a point at an infinite distance from all charges, where, by arbitrary definition, we may suppose the potential to be zero.

As the simplest and most useful case, let us calculate the electric potential due to an isolated positive charge  $e$  at a distance  $r$  from it.

Let  $O$  denote the position of the point-charge  $e$ . At a point  $P$

Fig. 14.

the electric intensity, *i.e.* the force on a unit positive charge, is  $e/(OP)^2$  and at a neighbouring point  $Q$  it is  $e/(OQ)^2$ . If  $P$  and  $Q$  are

taken very near together no sensible error will be made if the force throughout the distance  $PQ$  is taken as the geometrical mean  $e/OP \cdot OQ$ .

The work done in bringing a positive unit from  $Q$  to  $P$  is then

$$PQ \frac{e}{OP \cdot OQ} = (OQ - OP) \frac{e}{OP \cdot OQ} = e \left( \frac{1}{OP} - \frac{1}{OQ} \right).$$

Similarly, the work from  $R$  to  $Q$  is  $e \left( \frac{1}{OQ} - \frac{1}{OR} \right)$ , and from  $S$  to  $R$ ,  $e \left( \frac{1}{OR} - \frac{1}{OS} \right)$ .

Now, the total work done from  $S$  to  $P$  is the sum of the elements of work given above, and is therefore  $e \left( \frac{1}{OP} - \frac{1}{OS} \right)$ .

This process could be continued from as far as we please. If we imagine it begun at an infinite distance, the expression for the work done throughout, or the electric potential, becomes

$$V = e \left( \frac{1}{OP} - \frac{1}{\infty} \right) = \frac{e}{OP} = \frac{e}{r}.$$

This method of proof is known as integration, and, in the notation of the integral calculus, may be written

$$V = \int_{\infty}^r \frac{e}{r^2} dr = \frac{e}{r} - \frac{e}{\infty} = \frac{e}{r}.$$

Thus the potential due to a point-charge is proportional to that charge, and, since any distribution of electrification may be supposed to be made up by a collection of point-charges, it follows that, if all the charges in a system vary together, the potentials and the charges are always proportional to each other.

If the electric intensity be constant over a certain length  $l$ , then the work done in carrying a positive unit over the distance  $l$  is  $fl$ , and this is the difference of potential  $V$ . That difference is proportional to  $l$ , and thus, if the force be constant, the rate  $V/l$  of change of potential per unit length in the direction of the force is constant also, and equal to the electric intensity.

If the electric intensity be not constant, its value at any point will be equal to the rate of change of the potential at that point; that is, to the difference of potential over a small distance divided

by that distance, when the distance taken is so small that the force is sensibly constant over it.

The potential diminishes as we pass away from a positively electrified body, and the force on a positive unit is also directed away from such a body. Thus the resultant electric intensity acts in the direction in which the potential decreases. In general terms, the electric intensity in any direction is equal to the rate of fall of potential in that direction.

In terms of the differential calculus

$$f_x = -dV/dx \dots\dots\dots(3).$$

9. The charge on an isolated conductor is proportional to its potential, and the constant ratio between them, or the quantity of electricity needed to raise the potential by unity, is defined as the electric capacity of the conductor. Here the system is really made up of the conductor and the far-off surrounding conductors, which are taken to be at zero potential. We are, in fact, concerned, not with an isolated body, but with a system made up of the body, the dielectric field surrounding it, and the conducting boundaries of that field with an equal and opposite charge residing on them. The capacity  $C$  of this system is then given by

$$C = \frac{e}{V_1 - V_2},$$

where  $e$  is the charge on one boundary of the field, and  $V_1 - V_2$  denotes the difference of potential between the boundaries. A similar expression gives the definition of the capacity for systems such as condensers, which are essentially the same as the case just considered.

Cavendish again appears as the first to possess a clear idea of this quantity, and to make definite measurements of the capacity of different bodies. He constructed condensers by pasting tin-foil on each side of glass sheets, and arranging them in sets of three, so that one of the second set had the same capacity as three of the first set, and so on. As we shall see hereafter, the capacity of an isolated conducting sphere placed in air is numerically equal to its radius, and Cavendish used the diameter of a

sphere possessing the same amount of charge as the given body, when at the same degree of electrification, as the measure of its capacity. Thus when he says that a certain body contains  $n$  "inches of electricity" we may interpret his result as meaning that its capacity is  $\frac{1}{2}n$  inch.

The electric capacity of an insulated conductor is not a property of the form and dimensions of that conductor alone. It depends on the neighbouring conductors, and, as will be shown later on, on the nature of the dielectric or insulator separating it from the neighbouring conductors. The effect of one conductor on the capacity of another can be demonstrated easily by means of a gold-leaf electroscope. The divergence of the leaves measures the degree of electrification, *i.e.* the potential. If an uninsulated brass plate be held in the hand, and moved nearer to the plate at the top of the electroscope, the divergence of the leaves decreases, showing that their potential is diminished. No electric communication with the gold-leaf system has been made; hence the charge is unaltered and the capacity must have been increased.

10. Having given the laws of force and induction, the calculation of the distribution of charge on the surface of a conductor of any form is a question of mathematics.

Distribution of  
electricity on  
the surface of  
conductors.

For an isolated sphere, everything being symmetrical, the distribution is clearly uniform, the charge, as we have seen, residing on the outside of the sphere. As we pass over the surface of a conductor, places of great curvature will be found to be the most highly electrified. On sharp points, the surface density of electrification becomes very great; hence the power possessed by points of discharging a conductor.

The cases of an isolated ellipsoid, and of two spheres mutually influencing each other, were solved by Poisson, but it was reserved for Green to develop a more general method by means of which the distribution of charge on many other figures could be determined.

The next step was made by Lord Kelvin, who invented a new method—the theory of electrical images. When an otherwise isolated point-charge is placed in front of a plane or spherical

conducting surface, Lord Kelvin showed how to find the distribution of induced charge on the surface. The resultant electric intensity at points in the space in front of the plane conductor is the same as though the induced charge on the plane were replaced by a point-charge placed behind the plane in the position of the optical image of the original point-charge.

While such investigations are of great interest in the mathematical theory of electricity, they do not bear directly on the side of the subject considered in this book. With this brief reference we shall pass on.

11. Cavendish observed that coated plates of glass contained more charge than would be expected from their thickness and area when compared with similar systems of two metal plates separated by air. In certain cases, he gave numerical values for the ratio between the observed and the calculated charges, glass giving a value of about 8, and shellac about  $4\frac{1}{2}$ . This phenomenon was rediscovered and investigated carefully by Faraday. Faraday used the apparatus shown in Fig. 15, consisting of two concentric spheres, the space between which could be filled with air or any other fluid. Solid dielectrics such as shellac and glass were examined in the form of hemispheres, which could be placed in the lower half of the space between the spheres of the apparatus.

Two arrangements of this kind were made, exactly similar to each other. One was charged by connecting the inner sphere with a Leyden jar, and the degree of electrification tested by means of a torsion balance. The charge was then shared with the other apparatus, and the common potential again tested with the torsion balance. If the capacity of the two pieces of apparatus be the same, the potential of the doubled capacity will be half that of the single one with the same charge. This was found to be the case when both were filled with air, but, when a hemisphere of glass or shellac was interposed, the final potential

Specific  
inductive  
capacity or  
dielectric  
constant.

Fig. 15.

was less than half the original potential, showing that the final capacity was more than twice the capacity of the single apparatus filled with air. Allowing for the fact that only about half the inter-spherical interval was filled with the solid dielectric, Faraday calculated what the capacity would have been if the space had been filled completely. The ratio of this capacity to that of the apparatus when it contained air, was defined as the specific inductive capacity of the solid dielectric. In these experiments, Faraday discovered, with certain solids, a slow creep of electric charge into the substance of the dielectric. The result of measurements of the capacity of condensers thus depends on the time during which the condenser remains charged, and differences exist between dielectric constants as determined by long-charge methods, like that of Faraday, and short-charge methods such as will be described later (§ 69).

*Dielectric Constants. Specific Inductive Capacities<sup>1</sup>.*

Faraday could detect no difference between the specific inductive capacity of air at ordinary pressure and that of air at the lowest pressure he could reach. Electric forces act across the best vacuum we can obtain; exact experiments show that, taking the dielectric capacity of a vacuum as unity, that of air at atmospheric pressure is about 1·00059. For practical purposes, then, the value of the constant for air still may be considered to be unity.

It is easy to show, by direct experiment, that the force exerted by an electrified body on, for instance, a pith ball, is diminished by

<sup>1</sup> Taken from Prof. J. J. Thomson's *Recent Researches in Electricity*, p. 468.

the interposition of a solid dielectric such as a sheet of paraffin; and, as we shall see later, the effect observed in measuring capacities is explained if we write the force between the two point-charges as

$$F = \frac{e_1 e_2}{k r^2},$$

where  $k$  is Faraday's quantity, the specific inductive capacity or the dielectric constant. This, then, is the general expression for the law of force between electric charges. It is obvious that the corresponding value for the electric potential at a point due to a charge at a distance  $r$  must, in its general form, be written as

$$V = \frac{e}{k r}.$$

### SOME THEOREMS OF ELECTROSTATICS.

Total normal induction. Gauss' theorem. Electric force outside a uniformly charged sphere. Electric intensity outside a uniformly charged infinite plane. The electric capacity of an isolated sphere. Capacity of two concentric spheres. Capacity of two parallel planes. The mechanical force on a charged conductor. Energy of electrified systems. The quadrant electrometer.

**12.** IN deducing the mathematical theory of electrostatics from the result of experiment as formulated in the laws of force, we shall find the following theorem, due to Gauss, of great assistance.

**Total Normal Induction.**  
**Gauss' Theorem.**

Let us draw an imaginary closed surface, surrounding any quantity of electricity distributed in any manner. Then let us divide that surface into an immense number of very small elements of area, one of which is  $\alpha$ , and calculate the value of the electric intensity (or the electric force)  $N$  normal to each element of area. Assuming that the dielectric constant of the medium is  $k$ , we shall show that the value of the sum of all the areas multiplied by their corresponding normal forces, or  $\Sigma \alpha N$ , is equal to  $4\pi/k$  times the total quantity of electricity  $e$  enclosed within the surface. We may state this result in the form

$$\Sigma \alpha N k = 4\pi e.$$

The quantity  $\Sigma \alpha N k$  is called the total normal induction over the surface.

To simplify the equations, let us first take the medium to be air, for which  $k$  is unity.

Let  $PQ$  be the trace of one of the elements of area on the plane of the paper, and, at first, let all the charge be concentrated at the point  $O$ . With centre  $O$  and distance  $OP$  describe a sphere cutting  $OQ$  in  $R$ .

The element of area  $PQ$  being very small, the electric intensity over it is uniform, acts along  $PO$ , and is equal to

$\frac{e}{OP^2}$ . The component of this intensity

normal to the area is  $\frac{e}{OP^2} \cos QPR$ , since the angle  $QPR$  is equal to the angle between  $OP$  and the normal to the surface  $PQ$ .

Fig. 16.

Fig. 16 a.

Thus the product of the area and the normal force is

$$\text{Area } PQ \times \frac{e}{OP^2} \cos QPR = \text{Area } PR \times \frac{e}{OP^2}.$$

With centre  $O$  describe any sphere, cutting  $OP$  and  $OQ$  in  $A$  and  $B$ .

Then  $\text{Area } AB : \text{Area } PR :: OA^2 : OP^2$

or 
$$\frac{\text{Area } AB}{OA^2} = \frac{\text{Area } PR}{OP^2}.$$

Hence 
$$\text{Area } PR \times \frac{e}{OP^2} = \text{Area } AB \times \frac{e}{OA^2}.$$

Therefore the product of the element of area and its normal force is the same for the original imaginary surface as it is for this sphere round the point-charge as centre.

The same proof holds for all elements of area; and thus  $\Sigma \alpha N$  is the same for the surface as it is for the sphere.

For the sphere, the normal electric force is constant, and is everywhere equal to the electric intensity.

Hence

$$\begin{aligned}\Sigma \alpha N &= N \cdot \Sigma \alpha = N \cdot 4\pi (OA)^2 \\ &= \frac{e}{(OA)^2} \cdot 4\pi (OA)^2 = 4\pi e.\end{aligned}$$

This holds for the original surface also, and we establish Gauss' theorem,

$$\Sigma \alpha N = 4\pi e.$$

If the only electric charge in the field lies outside the surface, it is easy to see that the total normal induction must vanish.

For each of the areas  $pq$  and  $PQ$ , the product  $\alpha N$  is the same as for a sphere drawn round  $O$  as centre, and, in this case, the force at  $pq$  acts outwards from

Fig. 16 b.

the surface while that at  $PQ$  acts inwards. With reference to the surface, then, they have opposite signs, and, since they are equal, must cancel each other. In a similar manner, the forces due to other pairs of elements of area cancel, and thus the total normal induction due to the charge outside the surface must vanish also.

If the charge inside or outside the surface be distributed, instead of being concentrated at a point, it may be shown that similar results hold good. Any electric distribution can be represented as made up of a number of point-charges  $e_1, e_2, e_3 \dots$  etc. with electric intensities, normal to one single element of area, equal to  $N_1, N_2, N_3, \dots$  etc. The sum of these components is equal to  $N$ , the resultant component of the electric intensity normal to the area. Thus

$$\begin{aligned}\Sigma \alpha N &= \Sigma (N_1 + N_2 + N_3 + \dots) \alpha \\ &= \Sigma N_1 \alpha + \Sigma N_2 \alpha + \Sigma N_3 \alpha + \dots \\ &= 4\pi e_1 + 4\pi e_2 + 4\pi e_3 + \dots = 4\pi (e_1 + e_2 + e_3 + \dots) = 4\pi e.\end{aligned}$$

Therefore the total normal induction is equal to  $4\pi$  times the total charge within the surface however that charge be distributed.

If, instead of air, we have an insulating medium with dielectric constant  $k$ , the result becomes

$$\Sigma \alpha N = \frac{4\pi e}{k},$$

or

$$\Sigma \alpha N k = 4\pi e.$$

13. Let us find the electric intensity at a point  $P$  outside a uniformly electrified sphere, of which  $O$  is the centre.

Electric force  
outside a uni-  
formly charged  
sphere.

With centre  $O$  and distance  $OP$ , describe an imaginary spherical surface, and to this surface apply

Gauss' theorem,

$$\Sigma \alpha N = 4\pi e.$$

The surface being spherical, and the charged sphere within it being uniformly electrified, everything is symmetrical, and the normal force must everywhere be equal to the total force. Thus  $\Sigma \alpha N = f \Sigma \alpha$  where  $f$  is the electric intensity at the point  $P$ .

$$\text{Hence } f \cdot 4\pi (OP)^2 = 4\pi e$$

$$\text{or } f = \frac{e}{(OP)^2}.$$

Fig. 17.

It follows, therefore, that a uniformly electrified sphere exerts an electric force without it equal to that which the same quantity of electricity would produce if concentrated at the centre of the sphere.

We have supposed the sphere to be surrounded by air. In the general case, if it be immersed in a medium with a dielectric constant  $k$ , the intensity at the point  $P$ , without it, is seen to be

$$f = \frac{e}{k(OP)^2}.$$

Let us call the charge per unit area on the surface of the sphere the surface density of electrification, and denote it by the symbol  $\sigma$ .

The electric intensity just outside a sphere of radius  $r$ , *i.e.* indefinitely near its surface, is

$$f = \frac{e}{kr^2} = \frac{4\pi r^2 \sigma}{kr^2} = \frac{4\pi \sigma}{k}.$$

For a point indefinitely near it, the form of the surface does not matter, and this result therefore gives the electric intensity

just outside a charged surface of any form. It is known as Coulomb's law, and can be deduced directly from Gauss' theorem.

14. Let  $AB$  denote a part of a uniformly charged plane of infinite area. Outside the plane, with its axis normal to the plane, describe the cylinder  $PQ$ . From symmetry, the intensity must everywhere be normal to the plane, and uniform in any plane parallel to the charged one. There is thus no normal force over the curved sides of the cylinder, and the force is uniform and normal over the flat ends. If  $f_1$  and  $f_2$  be the intensities at the ends  $P$  and  $Q$  respectively, by Gauss' theorem,

$$\Sigma \alpha N = (\text{area } P \times f_1) + (\text{area } Q \times f_2) = 0.$$

Thus  $f_1 = f_2$ , since  $\text{area } P = \text{area } Q$ .

The intensity is therefore constant at all distances from the plane.

Describe another cylinder  $TS$ , with axis normal to the plane, enclosing an area  $\alpha$  of the plane, on which the total charge is  $\sigma\alpha$ . By Gauss' theorem

$$(\text{Area } T \times f_1) + (\text{Area } S \times f_2) = \frac{4\pi\sigma\alpha}{k}.$$

But

$$\text{Area } T = \text{Area } S = \alpha;$$

thus

$$2\alpha f = \frac{4\pi\sigma\alpha}{k}$$

or

$$f = \frac{2\pi\sigma}{k}.$$

It should be noted here that  $\sigma$  is the total amount of electricity on both sides of the plane per unit area. If  $\sigma$  be taken as the charge on one side of the plane only, then, for an isolated plane,

$$f = \frac{4\pi\sigma}{k}.$$

In this book we shall adopt the former convention, and use  $\sigma$  to denote the charge on unit area, counting in the charge on both sides of the plane.

Fig. 18.

**15.** We defined the capacity  $C$  of an isolated conductor, or rather the capacity of the system formed of that conductor and of the far-off boundaries of the dielectric medium surrounding it, as the charge  $e$  required to increase the potential  $V$  by unity. Hence

The electric capacity of an isolated sphere.

$$C = \frac{e}{V}.$$

The potential  $V$  is the difference of potential between the conductor and the far-off boundaries of the medium, which are defined to be at the zero of potential.

Since an isolated sphere is itself symmetrical and is affected equally on all sides by the action of other charged bodies, it must be electrified uniformly, and will therefore act at points outside as though its charge were concentrated at its centre. Thus the potential (§ 8) at its surface will be

$$V = \frac{e}{kr},$$

where  $r$  is its radius, and  $k$  the specific inductive capacity of the surrounding medium.

Hence

$$C = \frac{e}{e/kr} = kr.$$

Thus, in air, the capacity of an isolated sphere is numerically equal to its radius.

**16.** The capacity of two concentric spheres, with radii  $r_1$  and  $r_2$ , and a dielectric with constant  $k$  between them, is a quantity of practical as well as of historical interest. Let us suppose that a charge  $+e$  be given to the inner sphere, and that the outer sphere is connected with the earth. A charge  $-e$  will then be induced on it, since it surrounds the inner sphere completely. With regard to points outside both of them, each sphere acts as though its charge were concentrated at its centre. But the spheres have the same centre, and the charges are equal and opposite. Thus the potential just outside the outer sphere, and therefore the potential of its surface, must be zero.

Capacity of two concentric spheres.

The inner sphere, being a conductor, is an equipotential surface, and, since it is closed and contains no charge within it, there is no electric force inside, and the potential is everywhere the same. We may therefore find the potential of the inner sphere by calculating the value at the centre. Here the charge  $+e$  on the surface of the inner sphere is at a uniform distance of  $r_1$ , and the potential due to it is consequently  $\frac{e}{kr_1}$ . The charge  $-e$  on the outer sphere is at a uniform distance of  $r_2$ , so that the total potential of the inner sphere is

$$V_1 = \frac{e}{kr_1} - \frac{e}{kr_2} = \frac{e}{k} \left( \frac{1}{r_1} - \frac{1}{r_2} \right).$$

The capacity of the double system is, by what was said in § 9,  $e/(V_1 - V_2)$ , and we have seen that  $V_2$  the potential of the outer sphere is zero. Thus

$$C = \frac{e}{V_1 - V_2} = \frac{e}{\frac{e}{k} \left( \frac{1}{r_1} - \frac{1}{r_2} \right)} = \frac{r_1 r_2 k}{r_2 - r_1}.$$

17. Let  $AB$  and  $CD$  represent portions of two parallel planes of infinite extent. Let the area of each portion considered be  $\alpha$ . Let one plane be insulated and charged with a quantity of positive electricity till the surface density is  $\sigma$ . If the other plane be connected with earth, a negative charge will be induced on it. If we imagine the planes to be small portions of two concentric infinite spheres, we see that the charge on the part of the sphere  $CD$  which lies opposite the area  $AB$ , will acquire a charge numerically equal to that on the area  $AB$ . Thus the surface-density on  $CD$  will be  $-\sigma$ . Owing to the attractive forces between the opposite charges, the whole electrification on each plane will reside on the side nearest to the other plane.

Each plane will produce an electric intensity outside it equal to  $2\pi\sigma/k$  (§ 14). A positive unit placed between them will be repelled from one and attracted towards the other, so that the forces are in the same direction, and the total electric intensity between the

Fig. 19.

Capacity of  
two parallel  
planes.

planes is  $4\pi\sigma/k$ . Since we consider parts of infinite planes, everything is symmetrical, and the intensity is uniform. Thus the difference of electric potential  $V_1 - V_2 = ft = 4\pi\sigma t/k$  where  $t$  is the thickness of the dielectric stratum between the planes.

Now the capacity

$$C = \frac{e}{V_1 - V_2} = \frac{\sigma ak}{4\pi\sigma t} = \frac{ak}{4\pi t}.$$

This result is of great practical importance. As it stands, it gives an approximate value for the capacity of all condensers, in which a thin layer of dielectric lies between two conducting surfaces. If the dielectric is thin, the form of the surfaces is immaterial. Thus the capacities of Leyden jars, as well as those of plate condensers, may be calculated approximately from this formula.

Such arrangements, however, do not give us portions of infinite planes, and, if accurate results are needed, a correction must be applied to allow for the effects of the free edges of the system. This correction requires complicated mathematical treatment. In certain pieces of apparatus, however, it is possible to use a device due to Lord Kelvin, which makes the edge-correction unnecessary.

The insulated plane, let us suppose in the form of a circular plate, is surrounded by an annular disc, or guard ring, lying in the same plane, and separated only by a narrow air-gap from the central plate. The central plate and the ring can be connected by means of a fine wire, and then form part of the same conductor. In this state they are charged, and, since the irregularities due to the edges are confined to the guard ring, the electric distribution on the central plate  $ab$  is uniform. The wire is then removed, so that the central plate  $ab$  is insulated. We can thus deal with the charge on the central plate alone, and this charge is that calculated by the elementary theory of capacity given above. The use of a guard ring enables us to employ what are, in essence, portions of infinite planes.

Fig. 20.

The mechanical force on a charged conductor.

18. At a point indefinitely near the surface of a conductor, the neighbouring surface appears as a large plane; hence the electric intensity is normal to the surface, so that the mechanical force on a small area of the electrified surface will act along the normal.

The electric intensity  $f$  at a point  $P$  in the small area may be considered to be composed of a part  $f_1$  due to the charge on the small area, and of a part  $f_2$  due to the charges on the rest of the conductor and on other conductors in the field. Thus

$$f = f_1 + f_2.$$

As we pass from  $Q$  to  $S$ , points just without and just within the surface respectively, we change the sign of  $f_1$  the intensity due to the charge on the small area round  $P$ . Neither the sign nor the value of  $f_2$  will change, for, with respect to the more distant parts of the conductor, and to other conductors,  $Q$  and  $S$  are practically coincident points. Inside a closed charged conductor the intensity must vanish (§ 5). Hence at  $S$  the total intensity

$$f_2 - f_1 = 0.$$

Thus

$$f_1 = f_2 = \frac{1}{2}f,$$

where  $f$  is the total intensity outside the surface at  $Q$ .

Now the mechanical force on the small area  $\alpha$  in the direction of the normal is  $f_2\alpha\sigma$ , where  $\sigma$  is the surface density of electrification; for  $f_1$ , the intensity due to the charge on the area itself, cannot tend to move the area.

If, then,  $F$  be the mechanical force per unit area along the normal,

$$F\alpha = f_2\alpha\sigma = \frac{1}{2}f\alpha\sigma,$$

and

$$F = \frac{1}{2}f\sigma.$$

Since (§ 13) by Coulomb's law  $f = 4\pi\sigma/k$ ,

$$F = \frac{2\pi\sigma^2}{k} = \frac{f^2k}{8\pi}.$$

In the case of two parallel planes separated by a dielectric layer, the mechanical force on the central plate ( $ab$ , Fig. 20)

Fig. 21.

surrounded by a guard ring is of practical importance. The electric intensity due to the other opposite plane is  $2\pi\sigma/k$ , if the dielectric constant of the separating medium is  $k$  (§ 14). The charge on the plane  $ab$  produces no force on itself normal to its plane, thus  $2\pi\sigma/k$  is the force on a positive unit of charge placed on the plane  $ab$ . The actual charge is  $\sigma\alpha$ , and the mechanical force is  $2\pi\alpha\sigma^2/k$ .

It is more useful to express this force in terms of the difference of potential  $V_1 - V_2$  between the planes. The total intensity  $f$  between the planes, due to the charges on both, is  $4\pi\sigma/k$ , and the intensity is uniform, so that  $V_1 - V_2 = ft$ , where  $t$  is the distance between them. We may therefore write

$$V_1 - V_2 = 4\pi\sigma t/k$$

or 
$$\sigma = \frac{(V_1 - V_2)k}{4\pi t}.$$

The mechanical force on the area  $\alpha$  of  $ab$  is

$$F = \frac{2\pi\alpha\sigma^2}{k} = 2\pi\alpha \frac{(V_1 - V_2)^2 k^2}{16\pi^2 t^2 k} = \frac{\alpha k (V_1 - V_2)^2}{8\pi t^2}.$$

It is interesting to compare this equation with the expression (§ 11) for the mechanical force between two charges, viz.  $e_1 e_2 / kr^2$ . In any system, when the *charges* are constant, the forces are inversely proportional to  $k$ , and the substitution for air of a dielectric of high specific inductive capacity diminishes the forces. On the other hand when the *potentials* are kept constant, an increase of dielectric constant increases the mechanical forces between the parts of the system.

The expression for the force between two parallel planes is used in Lord Kelvin's Absolute or Trap-door Electrometer. In one form of this instrument, the moveable disc  $S$  is attached to three light springs, of which two are shown in Fig. 22. The disc usually lies rather above the plane of the guard ring  $AB$ . The plate

Fig. 22.

$CD$  is screwed up, till the attractive force pulls  $S$  into the plane of  $AB$ , as shown by a fixed sighting lens and a cross wire attached to  $S$ . The force then has a certain value, known from previous experiments on the weight needed to bring  $S$  to its sighted position. Hence the difference of potential between  $S$  and  $CD$  is determined:

$$V_1 - V_2 = t \sqrt{\frac{8\pi F'}{\alpha}},$$

the dielectric being air.

19. If no loss of energy occur, the energy of an electrified system must be equal to the work done against the electric forces during the process of charging. By the definition of electric potential, we know that, when unit positive charge is brought up to a conductor at a potential  $V$ , the work done against the electric forces is  $V$ , provided no appreciable change is thereby produced in the potential. Similarly if  $e$  units be brought up, the work done is  $eV$ . If  $e$  be small enough, the supposition of constant potential will be justified. Now we can imagine the process of charging an isolated conductor to be carried out by the successive addition of very small charges, and thus the electric work done may be written

$$W = e_1 V_1 + e_2 V_2 + e_3 V_3 + \dots\dots\dots$$

Let us represent this process graphically as in Fig. 23, where the ordinates represent potential and the abscissæ charge. The successive terms in the series just given are represented in the figure by the areas of the successive vertical strips, and the total electric work done is represented by the sum of these areas. If the magnitude of each successive charge be reduced without limit, this sum approximates to the area of the figure  $OPM$ .

Fig. 23.

Now by § 8 it follows that the potential of an isolated con-

ductor is proportional to the charge. Thus the curve  $OP$  is a straight line, and the figure  $OPM$  is a triangle. Its area is therefore  $\frac{1}{2}eV$ , where  $e$  is the final charge, and  $V$  the final potential. The electric work done in charging, and the electric potential energy stored in the conductor by virtue of its charge, are each given by

$$W = \frac{1}{2}eV.$$

An important case is that of the two parallel planes. The electrical energy is

$$W = \frac{1}{2}e(V_1 - V_2),$$

since this is the electrical work done in carrying a charge  $e$  from one plane to the other, producing thereby the difference of potential.

We can express this energy in terms of the dimensions of the apparatus, and either the potentials or the charges:

(i) Since the intensity  $f$  between the plates is uniform,

$$V_1 - V_2 = ft,$$

where  $t$  is the distance. Now  $f$  is  $4\pi\sigma/k$ , if  $k$  be the dielectric constant of the medium between the plates. Thus  $\sigma$  is  $\frac{fk}{4\pi}$ , and

$$\begin{aligned} W &= \frac{1}{2}\sigma\alpha(V_1 - V_2) \\ &= \frac{1}{2}\frac{fk}{4\pi}\alpha(V_1 - V_2) \\ &= \frac{V_1 - V_2}{t}\frac{k}{8\pi}\alpha(V_1 - V_2) \\ &= \frac{\alpha k}{8\pi t}(V_1 - V_2)^2 \dots\dots\dots(1). \end{aligned}$$

(ii) Again, we may express the energy in terms of the charge on one plate.

$$\begin{aligned} W &= \frac{1}{2}e(V_1 - V_2) \\ &= \frac{1}{2}e \cdot ft = \frac{1}{2}e \frac{4\pi\sigma}{k} t \\ &= \frac{1}{2}e \frac{4\pi e}{k\alpha} t \\ &= \frac{2\pi e^2 t}{k\alpha} \dots\dots\dots(2). \end{aligned}$$

Now by equation (1) we see that, if the potentials be kept constant, by connecting the plates to the poles of a battery or in some similar way, the energy of the system is inversely as the distance between the planes, and will therefore be increased if the distance be diminished. The attracting force between the oppositely charged planes tends to diminish the distance between them, but, if the potentials be kept constant, the system draws the necessary energy from the battery.

On the other hand, if the plates be insulated, so that the charges are constant, the system has no source of energy to draw upon, and thus the action which tends to occur under the natural forces, namely, an approach of the plates, must involve a decrease of available energy. This is also seen from equation (2), which shows that, in this case, the energy diminishes with the distance between the plates.

In the first case, where the potentials are kept constant, the effect on the energy of a small displacement of one plane towards the other is the difference between the energies before and after the displacement. Before the displacement, the energy is  $\frac{\alpha k (V_1 - V_2)^2}{8\pi t}$ , or writing  $V$  for  $V_1 - V_2$ , the energy is  $\frac{\alpha k V^2}{8\pi t}$ . After the displacement, the energy is  $\frac{\alpha k V^2}{8\pi (t - \delta t)}$ , when  $\delta t$  denotes a small change in the thickness  $t$  of the dielectric.

Since  $\delta t$  is a small quantity, this expression is equivalent to  $\frac{\alpha k V^2}{8\pi t} \left(1 + \frac{\delta t}{t}\right)$ , and the increase in the energy of the system during the displacement is  $\frac{\alpha k V^2 \delta t}{8\pi t^2}$ .

Putting  $V = 4\pi\sigma t/k$ , and  $\sigma = e/\alpha$ , we see that this expression becomes  $\frac{2\pi e^2 \delta t}{\alpha k}$ .

Now in the second case, when the charges are constant, the energy is  $2\pi e^2 t/k\alpha$ , and, after the same displacement, it becomes  $2\pi e^2 (t - \delta t)/k\alpha$ . Thus the decrease in energy of the system is  $2\pi e^2 \delta t/k\alpha$ . It follows that for a small displacement of the kind indicated, the increase of electrical energy, when the potentials are kept constant, is equal to the decrease of energy when the charges

are constant, and this, by the principle of the conservation of energy, when the system has no actual energy to draw upon, is equal to the external work which the system can do during the displacement. A general investigation shows that this result holds good for any kind of small displacement to which the system is subjected.

20. For many purposes, the best and most sensitive form of electrometer is the quadrant instrument invented by Lord Kelvin. A light spindle-shaped needle of aluminium or silvered paper is suspended by a fine wire or quartz fibre within a shallow box divided into four quadrants. The quadrants are supported on insulating pillars, which, in one recent form of the apparatus, are made of amber. Opposite quadrants are connected together by fine wires, and, in its position of equilibrium, the needle lies over the junction line between two quadrants.

Fig. 24.

The needle is charged to a high potential, and, if there be no difference of potential between the quadrants, the needle still lies in its median position. If, however, the opposite pairs of quadrants be connected with the terminals of a voltaic cell, or other source of potential-difference, the needle is deflected towards that pair of quadrants with the lowest potential, that is, with a relative electric

charge opposite to that on the needle. A mirror is attached to the needle, and the deflection measured by one of the usual optical methods.

Fig. 24 a.

In the form of electrometer shown in Fig. 24 *a*, the design of which is due to Dr F. Dolezalek, the suspension is a very fine quartz fibre, and is made into a conductor by coating it with a trace of a hygroscopic substance like calcium chloride, which always remains moist. The needle is of very light silvered paper, and the sensitiveness is so great that the needle need only be kept at a potential of 50 to 200 volts. A constant potential can be secured by connecting the fibre with one pole of a battery or dry pile, the other pole of which is put to earth. In older forms of the instrument, in which much higher potentials were necessary, the needle was charged initially by means of an electric machine or electrophorus, and was kept at a moderately constant potential by allowing a wire from it to dip in some sulphuric acid placed

in a little vessel coated with tin-foil. This vessel served as a Leyden jar, and its large capacity greatly retarded the fall of potential due to leakage from the needle.

The relation between the potentials and the deflection can be found by examining a simpler case consisting of a large plane

Fig. 25.

surface  $G$  moveable in its own plane over the two parallel co-planar surfaces  $E$  and  $F$ . If  $l$  be the width of the planes at right angles to the plane of the paper,  $Xl$  may be taken to denote the force tending to move  $G$  in the direction of the arrow. When  $G$  moves through a small distance  $x$ , the work done is  $Xlx$ . If the electrical system is isolated, so that the charges are constant, this work is equivalent to the decrease in the electrical energy of the system, while, if the potentials are kept constant, as is more usual in practice, it is equivalent to the increase in the electrical energy of the system (§ 19).

When  $G$  is moved through a distance  $x$ , the area of  $G$  opposite to  $F$  will be increased by  $lx$ , and the energy will be increased by

$$\frac{lx}{8\pi t}(V_N - V_{Q_1})^2,$$

where  $V_N$  denotes the potential of the needle  $G$ , and  $V_{Q_1}$  that of one quadrant  $F$ .

At the same time, the area of  $G$  opposite to  $E$  is decreased, also by  $lx$ , and a corresponding decrease of energy occurs equal to

$$\frac{lx}{8\pi t}(V_N - V_{Q_2})^2.$$

Thus the total increase in electrical energy at constant potential is

$$\frac{lx}{8\pi t}\{(V_N - V_{Q_1})^2 - (V_N - V_{Q_2})^2\}.$$

As we have seen, this is equal to the work done, therefore

$$Xlx = \frac{lx}{8\pi t} (V_{Q_1}^2 - V_{Q_2}^2 + 2V_N V_{Q_2} - 2V_N V_{Q_1}).$$

Thus 
$$X = \frac{1}{4\pi t} (V_{Q_2} - V_{Q_1}) \{V_N - \frac{1}{2}(V_{Q_1} + V_{Q_2})\}.$$

In this expression, the constant  $1/4\pi t$  depends on the particular case used for calculation, but the general form of the expression will be the same for the quadrant electrometer. Thus the couple tending to twist the needle will be proportional to

$$(V_{Q_2} - V_{Q_1}) \{V_N - \frac{1}{2}(V_{Q_1} + V_{Q_2})\}.$$

In practice, the potential of the needle is usually very high compared with that of the quadrants, and the couple will be proportional to

$$(V_{Q_2} - V_{Q_1}) V_N,$$

that is, to the potential of the needle and to the potential-difference between the quadrants.

This couple is opposed by the torsional couple in the wire or quartz fibre. The torsional couple is proportional to the angular deflection  $\mathfrak{S}$ . Thus

$$\mathfrak{S} = k V_N (V_{Q_2} - V_{Q_1}),$$

where  $k$  is some constant, to be found by experiment, depending on the form and dimensions of the instrument.

Quadrant electrometers are often used to measure large differences of potential by connecting one pair of quadrants with the needle. We then have  $V_N = V_{Q_2}$  and the general expression becomes

$$(V_N - V_{Q_1}) \{V_N - \frac{1}{2}V_{Q_1} - \frac{1}{2}V_N\} = \frac{1}{2}(V_N - V_{Q_1})^2.$$

Thus the deflection will be proportional to the square of the difference of potential between the needle and the one pair of quadrants.

This principle is employed in the electrostatic voltmeter illustrated in Fig. 26. Here two of the quadrants are removed, the axis of the needle is horizontal, and the lower end of the needle carries an adjustable weight. The needle is connected with the quadrants, and thus both are raised to the same potential.

It is obvious that the result is the same whether the system be positively or negatively electrified. Hence the electrostatic voltmeter, unlike some other forms, can be used to measure an alternating difference of potential.

In the multicellular voltmeter, the sensitiveness is increased by attaching a number of needles to a vertical axis, while quadrants lie between the needles.

## CHAPTER III.

### THE DIELECTRIC MEDIUM.

The importance of the dielectric medium. Lines and tubes of force. The energy in the dielectric medium. Analogy with a strained medium. Dielectric currents.

21. THE conspicuous success of Newton's formulation of the laws of gravitation suggested similar relations for electric forces, and, when the law of inverse squares was verified for electric forces also, it was inevitable that the analogy should be pushed as far as, or farther than, the case warranted. The gravitational attraction between two masses is independent of the nature of the intervening medium; and, forgetful or in ignorance of the experiment of Cavendish to which we have referred in § 11, natural philosophers till the time of Faraday assumed that electric forces also were not affected by the insulating medium across which they acted.

With an obstinate disbelief in the idea of action at a distance, Faraday set himself to examine the influence of the dielectric field. Guided by the hypothesis that the forces were somehow transmitted by the medium, he rediscovered the existence of specific inductive capacity, and, as we have seen, measured its value for several substances. He also showed by many experiments that electrostatic induction might occur in curved lines, whereas, on the theory of direct action at a distance, it should act in straight lines only. As a final result of his work, he framed a new theory of electric phenomena. He regarded them all as depending "on induction being an action of the contiguous particles of the

dielectric, which, being thrown into a state of polarity and tension, are in mutual relation by their forces in all directions."

Faraday's experimental researches in these subjects not only confirmed his original hypothesis, but still serve as an excellent example of the advantage, perhaps the necessity, of hypothesis as an aid to physical investigation even in the early stages of a course of experiment.

The centre of interest in electric science was thus shifted from the conductors to the dielectric or insulating medium. In Faraday's eyes, the essence of the phenomena was to be found in a state of strain set up by the action of the electric machine in the dielectric, the so-called electric charges on neighbouring conductors being merely the free surfaces of the strained medium.

**22.** In order to study the phenomena of the dielectric field,

Lines and  
tubes of force.

Faraday made use of the ideas of lines and tubes of force, conceptions which seem to have been suggested by the pattern assumed by iron filings when scattered on a card in a magnetic field (Fig. 27). Each filing, under the inductive action

Fig. 27.

of a magnet placed below the card, becomes a little temporary magnet; the filings set, each in the direction of the local magnetic force, and cling together to form chain-curves, the tangent to a curve at any point being in the direction of the resultant magnetic force at that point.

The corresponding lines of electric force, due to electrostatic

charges, cannot be demonstrated experimentally in such a simple manner, but their forms can be calculated from the law of force, and thus maps of the lines constructed for any simple case. A line of force is to be defined as a curve drawn so that, at each point, the tangent to the curve is in the direction of the resultant electric intensity at the point.

Two charges, equal in amount but opposite in sign, produce a simple field of force. Placed between them, an isolated unit point-charge of positive electricity will be repelled by one and attracted by the other. One line of force, then, must run straight from one of our charges to the other. At a point in the median plane, the vertical components due to the two charges will balance each other, and the horizontal components will again be in the same direction. Thus all lines of force cross the median plane in a horizontal direction. If we make the convention that a single line of force shall spring from one positive unit of electricity and end on one negative unit, the number of lines crossing any small area in the dielectric field normal to the lines will, as we shall see, be proportional to the resultant force at the area. We then arrive at the general picture of the lines shown in Figure 28, in which the resemblance to the corresponding case for magnetic lines is shown.

Fig. 28.

Figure 29 shows the distribution of the lines for two opposite charges, *A* being four times as great as *B*. Here, only part of the

lines springing from *A* end on *B*, the rest going to the walls of the room, or other conducting surfaces on which a negative charge can be induced.

Fig. 29.

In Figure 30 the lines of force arise from two equal positive charges of the same name, and all end on surrounding objects.

Fig. 30.

At the point marked *C* in Figure 29, and at a point midway between the charges in Figure 30, there is no resultant force.

If a tubular region of space be imagined as bounded by lines of force, it may be called a tube of force or a Faraday's tube. It must start from a positively charged conductor, and, according to our present convention, end on one negatively electrified. We may, if we please, suppose that each line of force in Figures 28 to 30 represents the axis of a Faraday's tube. It is usual to imagine one tube of force to spring from each positive unit of electricity. It will then end on a corresponding negative unit. By an application of Gauss' theorem, we may show that the normal induction over any cross-section of the tube is constant along its length.

In a future chapter we shall examine the effects of electric tubes of force in motion. From the magnetic field which then arises, we shall see some reason to modify our present conception of tubes of force. To explain the phenomena, we must then suppose that the positive tubes proceeding from positive charges, and the negative tubes springing from negative charges, all run off into space. Opposite tubes attract each other, and like tubes repel; and, as far as electrostatics is concerned, the result is exactly equivalent to that given by the more usual way of regarding the tubes. The usual method is somewhat more simple, and will be adhered to in this chapter.

The deduction of the exact distribution of the lines or tubes of force for complex cases requires mathematical analysis, but Faraday was able to investigate the general results by noticing that the lines behaved in every case as though they tended to shorten their length and spread as far from each other as possible—as though, that is to say, they were in a state of longitudinal tension and repelled each other laterally. It is well to reconsider Figures 28 to 30 from this point of view, and to learn to regard a resultant force, acting on a charged body, as due to the unbalanced effect of a one-sided excess of electric tubes in a state of tension.

We proved (§ 18) that on each unit area of a charged conductor there existed a mechanical force equal to  $f\sigma/2$ ,  $f$  being the resultant electric intensity, and  $\sigma$  the surface density of electrification. Now each line or tube of force is drawn from one unit

charge, so that  $\sigma$  denotes also the number of tubes of force proceeding from unit area. Hence the mechanical force on the surface is the same as though each tube exerted a pull equal to  $f/2$ . Thus the mechanical forces in the field are the same as though the tubes of force were in a state of tension, the tension in a tube at each point being measured by one-half the electric intensity at that point.

The electric intensity  $f$  just outside a charged surface is  $4\pi\sigma/k$ , and, since  $\sigma$  also denotes the number  $N$  of tubes of force per unit area, the electric intensity at any point of the field is  $4\pi N/k$ .

Thus 
$$N = \frac{fk}{4\pi}.$$

Hence the tension due to the tubes of force across unit area is

$$\frac{1}{2}Nf = \frac{f^2k}{8\pi}.$$

If the tensions were the only stresses in the field, the tubes of force obviously would all tend to gather together, and run in straight lines from the positive to the negative charges. In order to represent completely the state of the dielectric medium, in cases where the tubes of force are not straight, we must also suppose that the tubes repel each other, so that a lateral pressure exists at right angles to the lengths of the tubes. It may be shown by mathematical analysis that the requisite pressure also has the numerical value  $f^2k/8\pi$ , which is equal to the tension along the length of the tubes per unit area of cross-section.

**23.** As an example of a simple system, let us consider two parallel planes charged with equal and opposite quantities of electricity. The total energy is, according to § 19,

The energy in  
the dielectric  
medium.

$$W = \frac{1}{2}e(V_1 - V_2),$$

where  $e$  is the charge on one plane, and  $V_1 - V_2$  the difference of potential between the planes.

Since the electric intensity  $f$  between the planes is uniform,

$$V_1 - V_2 = ft,$$

where  $t$  is the distance between them. Now, if  $\sigma$  be the surface density,  $f$  is  $4\pi\sigma/k$ , and  $\sigma$  is therefore  $fk/4\pi$ . Thus the energy

$$\begin{aligned} W &= \frac{1}{2}\sigma Aft \\ &= \frac{f^2k}{8\pi} \cdot At. \end{aligned}$$

But  $At$ , the area of one plane multiplied by the distance between the planes, represents the volume of the dielectric stratum. Thus the energy per unit volume is  $f^2k/8\pi$ ; and this expression has a form which is independent of the particular limitations of the system chosen. At any point in a dielectric field, then, the energy residing in a surrounding volume, small enough for the intensity throughout it to be uniform, is  $f^2k/8\pi$  per unit volume.

**24** An elastic mechanical system, such as a spiral spring stretched by a load, possesses potential energy when strained, and one of the essential features of the electric theory, as formulated by Faraday and developed mathematically by Clerk Maxwell, consists in tracing the analogy between a dielectric medium subject to electric forces and a medium strained mechanically.

Analogy with  
a strained  
medium.

An elastic system, where the force  $F$  is proportional to the displacement  $x$ , possesses potential energy equal to the work done in stretching, which is  $\frac{1}{2}Fx$ . The expression for the electric energy per unit volume of insulator,  $f^2k/8\pi$ , may be written as

$$\frac{1}{2}f \cdot \frac{fk}{4\pi},$$

when its analogy with the mechanical energy

$$\frac{1}{2}F \cdot x$$

is manifest. Corresponding to  $f$  the electric force, we have  $F$  the mechanical force, and corresponding to  $x$ , the mechanical displacement, we have the quantity  $fk/4\pi$ , which, on this analogy, was called by Maxwell the electric displacement, though it is perhaps better described by Faraday's older name of dielectric polarization.

The view which locates the energy of an electric system in the dielectric medium must be regarded as one of the most important and fundamental conceptions in modern physical science. The

germ of the idea is to be found in Franklin's work, by which he showed that the charge of a Leyden jar or other condenser resided in the glass or other insulator which separated the two coatings. Cavendish, too, clearly recognised the effect of the dielectric on the capacity of his condensers.

But it is to the instructive genius of Faraday that we owe the first definite formulation of the new theory. As we have already stated, Faraday regarded induction as "an action of the contiguous particles of the dielectric, which, being thrown into a state of polarity and tension, are in mutual relation by their forces in all directions." It is not too much to say that this hypothesis was the guiding star in all Faraday's researches in electrostatic fields. The wonderful relations between apparently unconnected phenomena discovered by Faraday, Maxwell, and their followers, are the best evidence in favour of the trustworthiness of their faith.

Faraday had no facility in mathematical analysis, and his ideas, though fruitful indeed in his own case, only dominated the work of others when translated into definite mathematical form by his great successor Clerk Maxwell. If, as indicated above, the energy of the electric system resides in the dielectric medium, there should be an exceedingly minute fraction of a second required for an electric impulse to pass from one body to another—a time, during which, short though it may be, the energy is passing through the dielectric medium, and is unconnected in any way with conducting bodies. Such ideas led Maxwell to the theory of electromagnetic waves, and enabled him to calculate their velocity by methods we shall study hereafter. The concordance of the theoretical value of this velocity with the observed velocity of light, led directly to the theory that light is a series of electromagnetic waves in the dielectric luminiferous medium.

These ideas we shall examine in future chapters; here we are concerned chiefly with electrostatic phenomena. But, even in these phenomena, Faraday's views lead to modifications in our fundamental conceptions. Instead of fixing our attention on the charges, and forcing us to frame theories of incompressible fluids to explain the ideas in our minds, Faraday asks us to ignore the charges, and seek an explanation of electrostatic manifestations in the conception of energy residing in the dielectric medium, by virtue of stresses

and strains therein. The so-called charges on conductors in the electric field are but the free ends of the strained intervening substance. The charges serve to demonstrate the state of strain, as a spring balance, inserted into the middle of a stretched india-rubber cord, may be used to show the tension.

Electric forces can act across a vacuum, hence material media are not necessary. We are led to refer the stresses and strains here described to some all-pervading medium, which may be modified, but not excluded, by the presence of ordinary matter. We shall see later that the medium it is necessary to conceive in order to explain electric and magnetic phenomena is identical in properties with the medium required to explain light.

Faraday's tubes of force, and Maxwell's electromagnetic equations, fixed the centre of interest in the dielectric, till the work of the last few years has made it necessary to ask what happens at the ends of the tubes of force, and again to examine into the nature of the electric charges. To such points we shall return later.

25. Fig. 31 represents the system of tubes of force which connect the opposite plates of a parallel plane condenser. Most of these tubes run straight from one plate to the other, but, near the edges, tubes leak out, and some few join the back of the plates.

Dielectric  
currents.

Now let us suppose that the two plates are connected together

Fig. 31.

suddenly by means of a metallic wire. In a minute fraction of a second the condenser is discharged, and the whole system of tubes of force, representing the state of strain in the dielectric medium, vanishes.

In order to trace the process of their disappearance, three things must be borne in mind: (1) the tubes are in a state of tension, and thus tend to contract; (2) they repel each other laterally; (3) they end on conductors, the free ends of the tubes representing charges of positive and negative electricity.

While the condenser remains charged, the tubes of force are in equilibrium under their own tensions and pressures. When, however, a metallic connexion between the plates is established, the charges near the ends of the wire are free to move. That is to say, the ends of the tubes which are anchored to the charges (or, rather, which themselves constitute the so-called charges) drag their anchors. A tube of force with its ends at different points on the same wire will contract under its own tension, and its opposite ends will approach each other. The tube will shut up, and be obliterated.

The disappearance of one tube leaves the medium in a state of unstable equilibrium; the lateral pressure of that tube is removed, and neighbouring tubes will be pushed by the unbalanced pressure of other tubes successively into the wire. In this way the dielectric field is relieved of strain, and the tubes of force are destroyed.

During this process, a current of electricity is said to flow along the conducting wire. On the view we are now considering, that current is represented by the process of the tubes of force dragging the charges to which their ends are anchored along the wire under the tension of the tubes. The heat developed by the current is the result of the friction produced by the resistance of the conductor to the drag of these anchors.

In a later chapter we shall see that an electric current possesses something analogous to inertia, and that the process of discharge consists of a series of oscillations. The current alternates, and passes first in one direction and then in the other; it diminishes gradually in intensity till it dies away and the charges are dissipated.

The electric current is measured by the amount of charge passing per second, and, considering unit area of the planes, the current entering it is measured by the rate of change of  $\sigma$  the charge per unit area. Now, as we saw on p. 37,  $\sigma$  is equal to  $fk/4\pi$ , which itself (p. 55) represents the strain in the dielectric medium, or the dielectric polarisation.

Thus an electric current is represented by a change in the dielectric polarisation, and a circuit such as that we have been considering is completed by the dielectric medium. On the older view, the process of charging the condenser is imagined as the flow of the opposite charges along the two wires on to the plates, somewhat as two separate streams of water might be supposed to flow along two pipes into two reservoirs. On the theory of Faraday and Maxwell, we must imagine this process to be similar to a transient current flowing round a closed circuit till, owing to the strains in the dielectric medium, the opposing electromotive force set up in one part of the circuit becomes sufficient to produce equilibrium. In this part of the circuit no slip occurs, and all the energy put in remains as the potential energy of dielectric strain. In the wires, slip occurs with consequent friction, and the energy which enters sets up no opposing strain: it is all dissipated in the friction of electric resistance, and appears as heat in the conductor.

## CHAPTER IV.

### MAGNETISM.

Early history. Principal magnetic phenomena. Variation of magnetic force with distance. Interaction of two short magnets. Magnetic potential. Terrestrial magnetism. Magnetic induction. Experiments on magnetic induction. Theories of magnetism.

**26.** THE lodestone (or leading stone), a magnetic oxide of iron, was known to the ancients, and, since it was first found near the town of Magnesia in Lydia, received the name *μάγνης*. Lucretius appears to have known that the lodestone attracts iron, and that iron itself, when in contact with a lodestone, acquires magnetic properties.

The first practical application of magnetic properties was the invention of the mariner's compass, and, as so often happens, the interest aroused by a practical application led to a great development of the theoretical side of the subject.

It has been stated that the magnetized steel needle or mariner's compass was early known to the Chinese, but, however this may be, descriptions of it seem first to have appeared in European literature about the 12th century, coming probably from Saracenic sources, though the references indicate that it had been known for some time.

A compass-needle points not directly north and south, but in a magnetic meridian making an angle, called the declination or variation, with the geographical meridian.

Stephen Burrowes discovered that this angle changed in the course of a voyage; and, in 1683, Halley showed that the differences in the declination observed at sea were not due to the effect of neighbouring land, but must depend on the magnetic properties

of the earth as a whole. In 1698 he was appointed captain of an exploring ship, and, with this command, undertook a voyage which lasted two years, for the purpose of elucidating the phenomena of terrestrial magnetism. Halley, who afterwards succeeded Flamsteed as astronomer royal, also pointed out the importance of the slow secular change in the declination, which between 1580 and 1692 had changed from  $11^{\circ} 15'$  east to  $6^{\circ}$  west. The existence of smaller variations, both annual and daily, was noted by Graham about 1719.

About 1544 Georg Hartmann, vicar of St Sebaldus, Nuremberg, observed that a needle, pivoted to move freely in a vertical plane, dips down towards the north when magnetized by a lodestone. This dip was rediscovered in 1576, and carefully investigated by Robert Norman, a mariner, and in his own words, a hydrographer. Norman found that at London the angle of dip was  $71^{\circ} 50'$ . This angle too is subject to periodic change.

From 1540 to 1603 lived William Gilbert, of Colchester, who, besides the electrical researches to which we have referred in the first chapter, in his great work *De Magnete*, collected all that was then known on the subject of magnetism, and added many new and valuable observations. To Gilbert we owe the conception of the earth as a huge magnet, and the first exact studies which virtually founded magnetism as a science.

27. A steel needle, magnetized by stroking with a lodestone, and pivotted so as to be free to turn horizontally, sets in the magnetic meridian—its ends or poles point, one towards the north and one towards the south. The line joining these poles is known as the magnetic axis, and, for a thin needle, coincides with the geometrical axis. A magnetized mass of steel of whatever shape, however, still possesses a magnetic axis, which, if the mass were free to turn both vertically and horizontally, would always lie in the magnetic meridian.

With two pivotted compass-needles, it is easy to show that two north-seeking or two south-seeking poles repel each other, while two unlike poles attract each other. Here there is an obvious analogy with electric phenomena, but, unlike electric forces, magnetic effects are observed to any great extent with iron only, and

Principal  
magnetic  
phenomena.

act with equal intensity across the intervening medium whatever be its nature, provided it is not of iron. Screens of paraffin, ebonite, copper and all other non-magnetic bodies, produce no change in the force with which one magnet acts on another, though, as we have seen (p. 20), such screens diminish or destroy electric action. Again, an electric conductor can be given an isolated charge of positive or negative electricity, but a magnet must acquire an equal south-seeking pole when north-seeking magnetism is impressed upon it. In this respect, the substance of the magnet is more nearly analogous to the dielectric medium, at the boundaries of which equal and opposite electric charges are always to be found.

Just as electric charges are induced on conductors by the presence of charges in their neighbourhood, so magnetic poles appear on pieces of iron placed near a permanent magnet. A permanent north-seeking pole will induce a south-seeking pole on the nearer portions of a block of iron, and a north-seeking pole on the further portions. This explains the attractions observed between a permanent magnet and pieces of iron originally unmagnetized. Filings, for instance, will cling to the poles of a magnet and even form long chains: poles are induced on each filing and the opposite poles of neighbouring filings cling together.

A difference in behaviour between soft iron and steel becomes apparent at this stage of our experiments, and is of importance. The readily-induced magnetism on soft iron is temporary. If the inducing magnetic force be removed, the induced magnetism is destroyed by a very slight shake or shock, or by a small magnetic force in the reverse direction. With steel, on the other hand, while the induced magnetization is less intense for a given magnetizing force, it is much more permanent, and a considerable fraction of its intensity will survive even rough usage. Heating, however, will destroy all magnetization in any case. At a critical temperature of about  $700^{\circ}$  to  $900^{\circ}$  Centigrade, both iron and steel cease to be magnetic substances. On cooling, they regain their magnetic properties, but any actual magnetism they possessed before the heating will have disappeared.

The clinging filings to which we have referred, indicate clearly the points from which the forces originate, that is, the

poles of the magnet. The poles are not situated quite at the ends of the bar, but at points some little distance from the ends. Like the lines of electric force, magnetic lines of force may be defined as curves drawn through the magnetic field, so that, at each point of their length, the tangent to the curve gives the direction of the resultant local magnetic force. If filings are sprinkled over a card, below which a magnet is placed, pictures of the lines of force are readily obtained. A figure showing these lines has already been given to illustrate the idea of electric lines of force, and will be found on p. 50 (Fig. 27).

28. As in the case of gravitation and electric force, the magnetic force of a single pole is found by experiment to vary inversely as the square of the distance. So general is this form of law for all kinds of force acting from a point-source, that, from this group of

Variation  
of magnetic  
force with  
distance.

experiences alone, we might almost conclude that the inverse square law is a general property of our conception of space, rather than a relation depending on the nature of the particular forces.

A modification of the torsion balance enabled Coulomb approximately to establish the law in the case of magnetic poles, as well as in that of electric charges. The disturbing effects of the opposite poles, which must necessarily exist, and can only be removed to moderate distances, make the experiment somewhat inaccurate, and has led to the development of better methods.

All such methods depend on the measurement of the magnetic force at a point by means of the deflection of a magnetic needle from its normal position of equilibrium. Let  $NS$  denote the magnetic meridian of the earth and let a magnetic force  $F$  be applied along the magnetic east and west line, at right angles to the horizontal component of the earth's force, which we will denote by  $H$ .

The magnetic needle  $ab$  is thus deflected into the position shown, at an angle  $\theta$  with the meridian.

Fig. 32.

If  $m$  be the strength of each pole, the horizontal force on it due to the earth is  $Hm$ , and if  $l$  be the half distance between the poles of the needle, the couple due to the earth is  $2Hml \sin \theta$ . The couple due to the applied magnetic force  $F$  is  $2Fml \cos \theta$ . The quantity  $2ml$  constantly recurs in magnetic problems, and is known as the magnetic moment of the magnet. We shall denote it by the symbol  $M$ . It may be defined as the strength of one pole multiplied by the distance between the poles, and is clearly measured by the couple exerted on the magnet when placed at right angles to the magnetic force in a field of unit intensity.

When the magnetic needle we are considering is in equilibrium, we get

$$FM \cos \theta = HM \sin \theta,$$

or

$$F = H \tan \theta.$$

It will now be clear that we can compare two magnetic forces by comparing the deflections of the same compass-needle produced successively by the forces. For in each case

$$F = H \tan \theta.$$

If  $H$  be the same, the forces will be proportional to the tangents of the angles of deflection.

The most accurate verification of the law of force due to a magnetic pole is given by a method due to Gauss.

Let us assume the inverse square law, and compare some of its consequences with experiment. Let  $m$  denote the strength of either pole of a short bar magnet  $AB$ , and  $l$  the half length between its poles. At a point  $P$  on its axis produced, at a distance  $r$  from  $O$  the centre of the magnet, the total force

Fig. 33.

$$\begin{aligned} F_1 &= \frac{m}{(r-l)^2} - \frac{m}{(r+l)^2} = \frac{m \{(r+l)^2 - (r-l)^2\}}{(r-l)^2 (r+l)^2} \\ &= \frac{4mlr}{r^4 - 2r^2l^2 + l^4}. \end{aligned}$$

Neglecting terms involving the squares and higher powers of the comparatively small quantity  $l$ , we have

$$F_1 = \frac{2Mr}{r^4} = \frac{2M}{r^3}.$$

Now let us calculate the force at a point  $Q$  on the normal to the axis through the centre of the magnet. Let  $OQ$  be made equal to  $OP$  in the former experiment, and be denoted by  $r$ . The forces due to the two poles act along  $AQ$  and  $BQ$  respectively, and the resultant evidently acts from  $Q$  parallel to the axis of the magnet  $AB$ . The value of this force is the sum of the resolved components; thus

$$\begin{aligned} F_2 &= 2 \frac{m}{(AQ)^2} \cdot \frac{OA}{AQ} = 2 \frac{m}{r^2 + l^2} \cdot \frac{l}{(r^2 + l^2)^{\frac{1}{2}}} \\ &= \frac{2ml}{(r^2 + l^2)^{\frac{3}{2}}} = \frac{M}{r^3 \left(1 + \frac{l^2}{r^2}\right)^{\frac{3}{2}}}. \end{aligned}$$

Again neglecting terms involving  $l^2/r^2$ , we have

$$F_2 = \frac{M}{r^3}.$$

It follows, then, as a consequence of the law of inverse squares for the force due to a magnetic pole, that the force produced by a short magnet in the first, or so-called end-on position, is double the force in the second or broad-side-on position. Moreover, in each position, the force due to the whole magnet varies inversely as the cube of the distance from its centre. Both these results, it is evident, depend on the assumption that the force due to a single pole is that of the inverse square. If the force of a single pole varied as the inverse  $n$ th power of the distance, it is easily seen that the force due to the whole magnet, when it is short, would diminish in the ratio of the  $(n+1)$ th power, and the force in the end-on position would be  $n$  times that in the broad-side-on position. We should have

$$F_1 = \frac{nM}{r^{n+1}} \text{ and } F_2 = \frac{M}{r^{n+1}}.$$

In order to compare the magnetic forces produced by a magnet at equal distances in the two standard positions, a light mirror, with three or four pieces of magnetized watch-spring fixed behind it, may be suspended in a small glass case in the earth's field by a fine fibre of unspun silk. Its position of equilibrium is noted by reflecting a spot of light on to a scale. A short bar magnet is then placed successively east and west of the magnetometer mirror in the end-on position, and the mean deflection measured. The magnet is then placed with its centre successively north and south of the mirror in the broad-side-on position. The distance from the centre of the magnet to the centre of the mirror is in each case made as nearly as possible the same. It will be found that the tangent of the angular deflection in the first position is very nearly indeed twice the tangent of the angular deflection in the second position. Moreover, by changing the distance, it will be found that the tangent of the deflection varies inversely as the cube of the distance. We thus obtain an independent verification of the law that the magnetic force of a pole varies inversely as the square of the distance.

Fig. 34.

29. For the sake of example, let us consider two short magnets in the end-on position relatively to each other. Let  $r$  be the distance between their centres. The magnet  $AB$  produces a magnetic force  $2M/r^3$  at the part of the field where lies the magnet  $CD$ , and, if  $M'$  be the

Interaction of  
two short  
magnets.

Fig. 35.

moment of the magnet  $CD$ , the couple acting on it when deflected through an angle  $\theta$  is clearly

$$C = \frac{2MM'}{r^3} \sin \theta.$$

If, instead of the couple, we wish to find the force of translation when the two magnets lie end-on to each other as in Figure 35, we may proceed as follows. The force which  $AB$  exerts at a distance  $r$  from its centre is  $2M/r^3$ . The total force it exerts on the two poles ( $m'$  and  $-m'$ ) of the magnet  $CD$  is

$$\begin{aligned} F &= \frac{2Mm'}{(r-l')^3} - \frac{2Mm'}{(r+l')^3} \\ &= 2Mm' \frac{(r+l')^3 - (r-l')^3}{(r-l')^3 (r+l')^3}. \end{aligned}$$

And, neglecting squares and higher powers of the small quantity  $l$ ,

$$\begin{aligned} F &= 2Mm' \frac{6r^2 l'}{r^6} = 6M \frac{2m' l'}{r^4} \\ &= \frac{6MM'}{r^4}. \end{aligned}$$

Thus the forces vary inversely as the fourth power of the distance, while the couples vary inversely as the third power. These results hold whatever be the relative positions of the two magnets, though of course the absolute values of the couples and forces depend on the inclination of the magnets to each other. Similar investigations may be made for other positions.

**30.** The difference in magnetic potential between two points is defined as the quantity of work required to carry an isolated north-seeking magnetic pole of unit strength from one point to the other. The absolute potential of a point is then the amount of work required to bring such a pole against the magnetic forces from a place of zero potential (or from infinite distance) to the point considered, on the assumption that the strength of the pole is small enough not to affect the magnetic field.

The investigation given in § 8 for the electric potential of a point in air, at a distance  $r$  from an electric charge  $e$ , applies, with the necessary change of symbols, to the case of the magnetic potential of a point in air or any other non-magnetic medium. The magnetic potential is  $m/r$ , where  $m$  is the strength of an isolated magnetic pole at a distance  $r$  from the point.

To find the potential due to a short complete magnet, we must consider the combined effect of its two poles at a point  $P$  outside it. Join  $P$  with  $O$  the centre of the magnet, and let the angle between  $OP$  and  $AB$ , the magnetic axis of the magnet, be  $\theta$ . From  $A$  and  $B$  draw straight lines  $AM$  and  $BN$  at right angles to  $OP$  or  $OP$  produced.

Fig. 36.

The potential at  $P$  due to the pole  $B$  is  $m/BP$ , and that due to the pole  $A$  is  $-m/AP$ . Thus, if  $OP$  be denoted by  $r$ , and  $OA$  or  $OB$  by  $l$ , the potential  $V$  at  $P$  due to the magnet is given by

$$V = \frac{m}{PN} - \frac{m}{PM} = \frac{m}{r - l \cos \theta} - \frac{m}{r + l \cos \theta},$$

or, neglecting terms involving the squares of the small quantity  $l$ ,

$$V = \frac{2ml \cos \theta}{r^2} = \frac{M \cos \theta}{r^2}.$$

### 31. The investigation of the

**Terrestrial  
magnetism.**

distribution of the  
earth's magnetic force

can now be described. The total force, at any place on the earth's surface, acts at a certain angle with the horizontal known as the dip, and at a certain angle with the geographical meridian called the declination. The total magnetic force can be determined in magnitude and direction by measuring these two angles and the absolute value of the horizontal component.

Figure 37 shows a declinometer. The magnet consists of a hollow

Fig. 37.

tube, at one end of which is placed a piece of plane glass with a scale on it, and at the other a lens with a focal length equal to the length of the magnet-tube. Light from the scale will then emerge from the lens as a parallel beam. The magnet is suspended by a single torsionless fibre of unspun silk. The position of the geometrical axis of the magnet is determined on the glass scale. The magnet is then turned upside down and resuspended. The mean of the two positions of the geometrical axis, as observed in the telescope, gives that of the magnetic axis, and its direction relative to that of some external object is found by means of the scale at the foot of the instrument.

A dip-circle is shown in Figure 38. The plane of the circle is set in the magnetic meridian, and the dip observed. To eliminate the error arising from the axle of the needle not

Fig. 38.

coinciding with the centre of the circle, the positions of both ends of the needle are read; to avoid the error due to the magnetic axis not coinciding with the line joining the ends of the needle, the needle is reversed, so that the face originally pointing east now

turns to the west; to avoid the error due to the centre of gravity not falling in the line of the axle, the needle is remagnetized, its

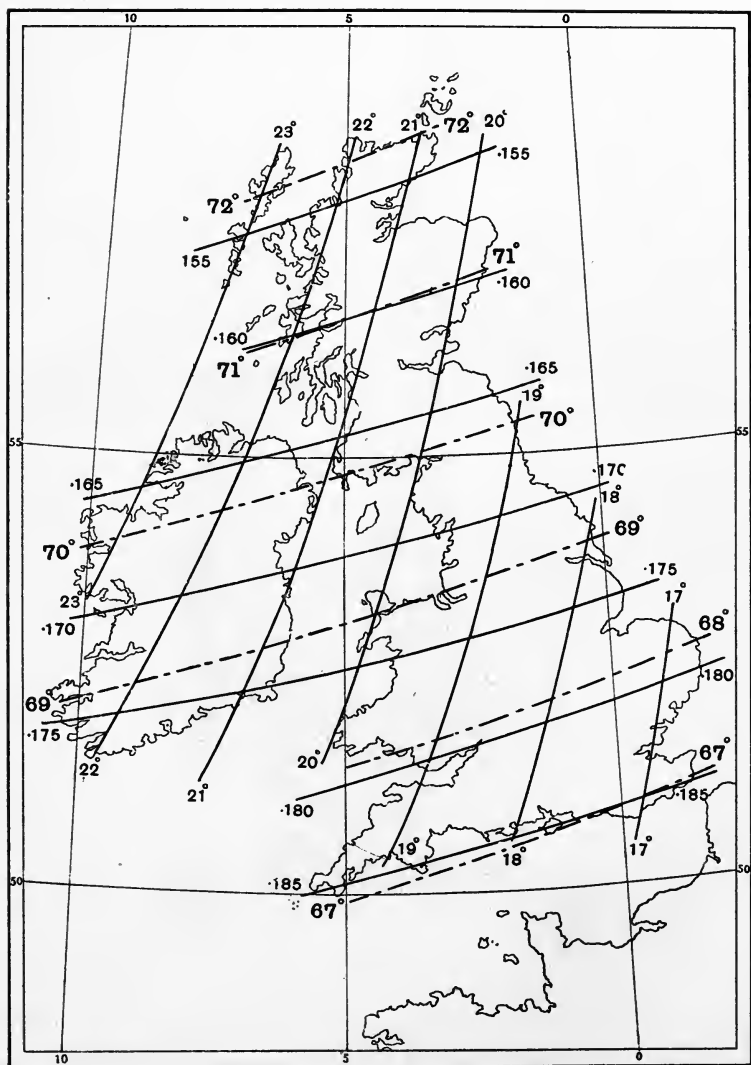

Fig. 39.

poles reversed, and a fresh set of observations made. The mean of all these results is taken as the true dip.

Both the declination and the dip vary from place to place over the surface of the earth, and the results of such measurements as we have described may be exhibited by maps, on which places of equal declination and places of equal dip are joined by isogonic and isoclinic lines respectively. Another series of lines may be drawn through places of equal horizontal magnetic force. These lines, together with isogonic and isoclinic lines are shown in Figure 39.

A different system of directional lines is due to Duperrey, and consists of a series of lines traced by starting from any point and following the direction of the compass-needle.

The slow secular changes in the magnetic angles at London are shown in the subjoined table :

Date	Declination	Dip
1576		71° 50'
1580	11° 15' E.	
1600		72° 0'
1622	6° 0' E.	
1657	0° 0'	
1672	2° 30' W.	
1676		73° 30'
1723	14° 17' W.	74° 42'
1773	21° 9' W.	72° 19'
1787	23° 19' W.	72° 8'
1802	24° 6' W.	70° 36'
1820	24° 34½' W.	70° 3'
1860	21° 39' 51" W.	68° 19'
1893	17° 27' 0" W.	67° 30'
1900	16° 52' 40" W.	

Besides these slow secular changes, diurnal variations of several minutes of angle are observed. Moreover, rapid and irregular changes, known as magnetic storms, frequently occur, often simultaneously with the formation of a sun-spot, and the occurrence of brilliant auroral displays. Such variations are recorded at magnetic observatories by means of suspended needles, which, through the use of mirrors, are made to record photographically the magnetic changes.

By examining the relation which exists between the horizontal and vertical components of the earth's magnetic force, it has been shown that the mean values of the magnetic elements are determined by causes below the surface of the earth, but that the diurnal variation and magnetic storms are due principally to changes going on above the surface—perhaps to electric currents in the rarefied upper regions of the atmosphere.

Having determined the angles of declination and dip, we still require to measure the magnitude of the horizontal component  $H$  of the earth's magnetic force, in order to be able to specify completely the magnetic state of a given place.

We showed in § 28 that, at a point on its axis at a distance  $r$  from the centre of the magnet, a short bar magnet produced a magnetic force equal to  $2M/r^3$ . If, then, such a magnet be placed with its axis east and west, it will deflect a small compass-needle placed on its axis through an angle  $\theta$ , given by the relation

$$\frac{2M}{r^3} = H \tan \theta \dots \dots \dots (1).$$

The angle  $\theta$  may be determined accurately by fixing the compass-needle to a mirror, and observing the deflection of a spot of light.

We thus obtain one relation between  $M$ , the magnetic moment of the deflecting magnet, and  $H$ , the horizontal component of the earth's force. To get a second relation, the bar magnet may be suspended by a torsionless silk fibre in an instrument resembling the declinometer of Figure 37 on page 68. The magnet is then set oscillating through a very small angle about a vertical axis, and its time  $T$ , of complete oscillation, measured with a chronometer. The restoring couple is  $HM \sin \theta$ , and, since  $\theta$  is small, the couple for unit angular displacement is  $HM$ . Hence, from the usual formula for harmonic vibrations, we have

$$T = 2\pi \sqrt{\frac{K}{HM}} \dots \dots \dots (2).$$

The moment of inertia  $K$  may be calculated from the mass and dimensions of the magnet, and we then obtain the value of  $H$

from the following expression, which may be deduced from equations (1) and (2) given above,

$$H^2 = \frac{8\pi^2 K}{T^2 r^3 \tan \theta},$$

while  $M$ , the magnetic moment of the bar magnet, is given by the relation

$$M^2 = \frac{2\pi^2 K}{T^2} r^3 \tan \theta.$$

Having thus found  $H$ , the horizontal component of the earth's magnetic force, by observing  $i$  the angle of dip, we know the total magnetic intensity  $I$  and the vertical component  $V$ , for

$$I = \frac{H}{\cos i},$$

and

$$V = I \sin i = H \tan i.$$

Fig. 40.

**32.** It is well known that magnetic substances like iron, when subjected to a magnetic force, themselves become magnetized. Nickel and cobalt show similar properties, though to a much smaller degree. In all these cases, a north-seeking pole, presented to one end of a bar of the metal, induces a south-seeking pole on the nearer end. Attraction results, and the magnetized bar tends to move into the stronger parts of the field.

If we examine a bar of bismuth in the same way, using a very powerful electromagnet to produce an intense magnetic force, these phenomena are reversed. A pole of the same name as the inducing pole appears on the nearer end of the bismuth bar, and repulsion follows. Bismuth always tends to move into the weaker parts of the field; it is called a diamagnetic substance, while iron and its like are known as paramagnetic substances.

By the use of the intense magnetic fields produced by powerful electromagnets, all bodies may be shown to possess some slight trace of magnetic properties. It is remarkable, however, that iron shows these phenomena to a very much greater degree than any other material known; unless an exception be made at some future

time, in favour of certain rare metals such as erbium and others, which, should they be obtained in a pure form, seem likely to equal or exceed the susceptibility of iron.

Conditions of temperature exercise a determining influence in all cases of substances which respond to magnetic forces. Iron at ordinary temperatures is in many respects a different substance from the non-magnetizable metal into which it is transformed above its critical temperature; its magnetization, however intense, almost entirely disappears within a range of a few degrees' increase of temperature, and very marked alterations then take place also in many of its other properties, such as its specific heat and electrical conductivity. Nickel and cobalt are also affected by temperature in varying degrees; and certain alloys, notably those of iron and nickel, exhibiting two critical temperatures, have shown such great changes in magnetic properties with a change of temperature that they may be said to exist in two conditions, one of which is magnetic and the other not. In short, the magnetic properties of any substance depend on the quality of the substance itself, the amount of magnetization, and on the temperature.

The magnetization induced on a given bar of iron is evidently measured by the resulting magnetic moment; but it is convenient to have a unit which depends on the material only, and not on the shape or dimensions of a particular bar. Hence we form the conception of *intensity of magnetization*, and define it as the magnetic moment per unit volume. The ratio of the intensity of magnetization to the magnetic force producing it is called the *magnetic susceptibility*. It should be said that the magnetic force of this definition is the magnetic force actually effective within the substance of the iron. Owing to the magnetism induced at the ends of a piece of iron the effective magnetic force is less than that applied externally, and depends on the shape of the iron. This result is considered below in § 33. The magnetic susceptibility is not a constant, but depends upon the value of the magnetizing force.

The magnetic force is defined as the mechanical force on a unit north-seeking magnetic pole, and, as long as the force is measured in air or other non-magnetic substance, this definition is free from ambiguity. When, however, the force is to be measured in iron,

it is necessary to imagine that we cut a cavity in which to insert the measuring pole, and the resultant force on the pole will depend on the shape of the cavity. Where the lines of force leave iron and enter the cavity, a north-seeking pole is induced, and where they re-enter the iron, a south-seeking pole. If the cavity is a cylinder with its axis along the lines of force and its breadth very small compared with its length (Fig. 41), the effect of the ends is negligible, and the force within the cavity is still defined as the magnetic force.

Fig. 41.

Fig. 42.

If we take the other extreme case, and imagine the cavity in the form of a narrow thin crevasse, with its plane normal to the lines of force (Fig. 42), the effect of the induced poles on the opposite faces of the crevasse becomes very marked. The intensity  $I$  of magnetization is defined as the magnetic moment per unit volume of the iron. If we consider a certain volume of the iron in the form of a rectangular block with one face on the side of the crevasse, we have

$$I = \frac{M}{La},$$

where  $L$  is the length of the block,  $M$  its magnetic moment, and  $a$  the area of its face on the crevasse. But the magnetic moment of the block is defined as the strength of one of its poles multiplied by its length. Thus

$$I = \frac{mL}{La} = \frac{m}{a},$$

a result which shows that, in such a case, where the magnetism of the pole may be regarded as uniformly distributed over the end of the iron, the intensity of magnetization is equal to the strength of pole per unit area, that is, to the surface density of the magnetism.

The analogy between the crevasse in the iron and two parallel metallic plates charged with opposite kinds of electricity to a surface density  $\sigma$ , will now be apparent, and by § 17 we see that the magnetic force between the two faces, due to the magnetism on them, is  $4\pi I$ . The total force on a unit pole in the crevasse will be the sum of this quantity and the original magnetizing force  $H$ , and this total force is defined as the *magnetic induction*, and usually written as  $B$ . If the direction of the magnetic induction coincides with that of the original magnetizing force, as we have supposed, we get the relation

$$B = H + 4\pi I.$$

We have already defined the quantity known as the magnetic susceptibility  $k$  as the ratio  $I/H$ . Thus

$$\begin{aligned} B &= H + 4\pi Hk, \\ &= H(1 + 4\pi k). \end{aligned}$$

The ratio of the magnetic induction in the iron to the magnetizing force is a useful quantity, and is called the *magnetic permeability*,  $\mu$ . Therefore  $\mu$  is  $B/H$ , and we get

$$\mu = 1 + 4\pi k$$

as the relation between the permeability and the susceptibility.

We have considered already the general form of the lines of magnetic force, and traced their analogy with the corresponding lines of electric force. On page 53 we developed the idea of lines of force into that of tubes of force, and agreed to imagine one tube of force as springing from one unit of positive electricity and ending on one negative unit.

With regard to lines of magnetic force, a different convention is adopted. Instead of drawing one line or tube of magnetic force from each unit of magnetism, we draw through unit area in the field, normal to the direction of the magnetic force, a number of lines of force equal to the numerical value of the magnetic force at that position. Throughout regions of the field in which there are no magnetic substances, the lines of force will be continuous.

When magnets, or magnetic substances, are present, further consideration is necessary.

The laws of magnetic force are similar to those of electric force, and Gauss' theorem, § 12, and the deductions from it, hold equally in the case of magnetism. Moreover, as we shall see presently, the magnetic permeability  $\mu$  corresponds with the dielectric constant  $k$ . Let us draw round an isolated magnetic pole an imaginary sphere. By analogy with the electric case considered in § 12, we then have the relation

$$\Sigma \alpha H \mu = 4\pi m,$$

where  $H$  is the normal magnetic force on each element of area of the sphere, and  $m$  the quantity of magnetism within the sphere, that is, the strength of the magnetic pole.

Now the quantity  $H\mu$  is, by definition, equal to  $B$  the magnetic induction in the medium, and hence  $\Sigma \alpha H \mu$  is  $\Sigma \alpha B$ , a quantity which clearly represents what we must call the total magnetic induction over the surface of the sphere.

If we imagine the magnetic pole to be placed in air, and surrounded by a hollow spherical shell of iron, we could still apply Gauss' relation to the external surface of the shell in the form

$$\Sigma \alpha B = 4\pi m.$$

Drawing tubes of induction from the pole to inclose proper elements of area, we see that the quantity  $B$ , the induction, is continuous throughout such a tube whether it passes through one medium or through more than one. This shows the importance of the conception of magnetic induction: it is the vector quantity which is continuous throughout any magnetic field.

If we draw through unit cross area surrounding a point a number of tubes of induction equal to the value of the magnetic induction at the point, in accordance with the usual convention, it should be noticed that the number of tubes through an area  $\alpha$  is  $\alpha B$ . Hence, the total number of tubes proceeding from a pole of strength  $m$  is  $4\pi m$ , and, from a pole of unit strength, the number is  $4\pi$ . This result should be compared with the electrical convention, by which one tube of electrostatic induction is imagined to spring from unit charge of electricity.

These relations may be considered profitably from another point of view, by supposing a narrow gap cut in an iron circuit otherwise continuous. Let us take, for instance, the case of a ring of iron, round which a continuous magnetizing force is exerted by the action of an electric current circulating in coils wound over the ring. Across a thin cut in the iron, the lines of force will run from one side to the other, and, if the cut be indefinitely thin, an indefinitely small number of lines of force will escape at the edges of the cut<sup>1</sup>. All the lines may then be imagined to run straight from one side to the other. The magnetic induction in the cut is

Fig. 43.

$$B = \mu H = H (1 + 4\pi k).$$

But, as we have seen above, of this induction,  $H$  is due to the magnetizing force, and  $4\pi kH$ , or  $4\pi I$ , is due to the induced magnetism on the faces of the cut. But  $I$  is measured by the quantity of magnetism  $m$  per unit area, and thus from each unit of area the amount of induction is  $4\pi m$ . Now, as stated, the conventional mode of drawing magnetic lines of force is to draw through unit area, normal to their direction in the field, a number of lines equal to the force at that place. Thus, in the case now under consideration, from each unit of area of the cut,  $4\pi m$  lines proceed. From a unit pole, then, the number of magnetic lines of force is  $4\pi$ , in accordance with the result already obtained.

The lines crossing unit area of such an ideal cut represent the magnetic induction across the cut, and, also by what was said on page 75, the induction in the iron across any section of the ring, for it is possible to imagine an indefinitely thin crevasse cut anywhere round it. Thus continuous lines of magnetic induction

<sup>1</sup> In practice there would always be considerable leakage of lines, for a cut of any finite thickness would throw back the poles some little distance from the faces of the cut. This, however, does not affect the reasoning given in the text, which is based on ideal conditions.

may be imagined to pass round the ring, and across the intervening gap. In air, these lines are also lines of force, but in iron the lines of force would be  $\mu$  times less in number than the lines of induction, and, in crystalline media, need not necessarily coincide with them in direction.

The induction  $B$  in the air gap is the force acting on a unit north-seeking magnetic pole placed therein. In the iron the induction is also  $B$ , since it is continuous. But  $B$  is  $\mu H$ , and thus the magnetic force in the iron is  $\mu$  times less than in air.

The permeability  $\mu$  in magnetism is now seen to be analogous to the specific inductive capacity or dielectric constant  $k$  in electrostatics. Just as the electric force in paraffin is  $k$  times less than in air, so the magnetic force in iron is  $\mu$  times less than in air, and the complete expression for the force between two magnetic poles separated by a distance  $r$  is

$$F = \frac{m_1 m_2}{\mu r^2}.$$

While, however, the dielectric constant does not vary when the electric force is changed, the permeability, as we shall see, depends on the applied magnetic force.

Another analogy, between the magnetic permeability of iron and the specific electric conductivity of an electric conductor, is useful in the theory of electromagnetic machinery, and will be considered in § 57, Chap. VII.

The conception of lines of magnetic induction is of great importance in electromagnetic theory, and will be used largely in Chapter VII. It should be noted that while electric or magnetic lines of force begin and end on electric charges or magnetic poles, magnetic lines of induction have neither beginning nor end, but form continuous closed curves.

The induction, by one pole of a permanent magnet, of an opposite pole on a piece of iron in its neighbourhood will cause the lines of force from the one pole to concentrate on the other, just as the lines of force from the north-seeking pole of a magnet in Figure 27 on page 50 concentrate on the south-seeking pole. It follows that a piece of soft iron, placed in a uniform magnetic

field, deflects the lines of induction so that they crowd through the iron. For certain cases it is possible to calculate this effect, and Figure 44, derived from Lord Kelvin's Reprinted Papers, shows

Fig. 44.

the distribution of lines of electric force in the analogous system of a sphere of some dielectric substance, with a specific inductive capacity greater than unity, placed in air in a uniform electric field. The figure represents equally well the magnetic lines of induction through a paramagnetic substance such as iron, placed in a uniform magnetic field. When the permeability is very great, the magnetic induction inside the sphere is  $3H$ , where  $H$  is the magnetic force in the undisturbed uniform field outside, while the magnetic force in the iron is  $3H/\mu$ —a value very small compared with that without.

Owing to this concentration of the lines of induction in paramagnetic substances, thick iron screens may be used to protect galvanometers or other magnetic instruments from the influence of an external field. The shielding effect is much less complete than the electrostatic shielding of conducting screens (p. 20), for an electric conductor is analogous to a substance of infinite magnetic permeability.

- 33.** In order to examine the magnetic properties of a sample of iron, certain precautions are necessary. When a bar of iron is placed in a magnetic field, poles are induced near its ends, and these poles will themselves exert a

magnetic force on the substance of the bar. It is evident from Figure 45 that the force due to the induced poles acts in the iron in the direction opposite to that of the inducing force, and thus a demagnetizing effect is

Fig. 45.

produced. With a short, thick bar this effect is considerable. The magnetizing force which really acts on the iron is less than that applied externally, and the resultant induced magnetization is less than would be expected. The results of many early experiments are useless from this cause.

The effect of the ends can be eliminated in several ways. We may, if we please, use an endless ring of iron, and observe its influence on the electromagnetic induction of currents in coils wound over it by methods that will be described in Chapter VII.

We may, however, in certain cases, use iron rods, apply a constant magnetizing force, and measure the resultant magnetization by the usual deflection methods. If a bar in the form of an elongated ellipsoid is used, it is possible to calculate the reverse effect of the induced poles near the ends, or, by taking a long, thin wire, with a length two or three hundred times the diameter, the effect of the ends is so small that, in ordinary work, it may be neglected.

We shall show in the next chapter that inside a long helical coil of wire, called a solenoid, the magnetic field of force is uniform, and equal in strength to  $4\pi nc$ , where  $n$  is the number of turns of wire per unit length, and  $c$  is the electric current flowing in the coil measured in electromagnetic units.

An iron wire, or bundle of iron wires, placed inside a solenoid so that the coil well covers the ends, will therefore be subject to a uniform magnetic force of known and controllable strength.

At a considerable distance from the solenoid, at a point on its axis produced, is placed a magnetometer, consisting of a suspended needle and mirror as shown in Figure 34 on page 66.

The current is passed in series through the solenoid, and through a small coil which is moved about till, whatever current be passed, it just balances the effect of the empty solenoid on the magnetometer needle. The iron is then inserted in the solenoid,

and a small current passed round the coils. The deflection of the needle is due to the iron alone, and the magnetic moment  $M$  of the iron is given by the relation deduced on page 72, namely

$$M = \frac{r^3 H \tan \theta}{2},$$

where  $H$  is the horizontal component of the earth's magnetic force,  $r$  the distance of the needle from the centre of the iron, and  $\theta$  the deflection of the needle. By determining the length and diameter of the iron wire, its volume  $V$  is known, and the intensity  $I$  of magnetization may be calculated, for  $I$  is  $M/V$ . The susceptibility  $k$  of the iron is the ratio of the intensity of the magnetization to the magnetizing force  $H$ , the permeability  $\mu$  is  $1 + 4\pi k$ , while the magnetic induction  $B$  is the product of  $\mu$  and  $H$ .

Another method, already referred to, which in some cases is more convenient, depends on the induction of a secondary electric current in one coil of wire by a variation of a primary current in another coil in the neighbourhood. If both coils are wound over an iron core, the induced electromotive force, being proportional to the rate of change of the magnetic induction, gives a means of measuring the properties of the iron. This method is explained in § 53, Chapter VII.

The results of such experiments, by whichever method conducted, can be represented graphically by plotting abscissæ proportional to the magnetizing force  $H$ , and ordinates proportional either to the magnetic induction  $B$ , or to the intensity of magnetization  $I$ .

Figure 46 shows a curve, obtained by Prof. Ewing, giving the magnetic induction. When the magnetic force is small, less than about one-tenth of the earth's horizontal force, the induction in demagnetized iron increases nearly in proportion to the force, as shown near  $O$  in the figure. Then it rises much more quickly, but finally increases from  $A$  onwards more and more slowly, till, at the highest forces possible, the induction is only increased very slowly by the farther increase of magnetic force, as from  $G$  to  $P$  in the figure; here the intensity of magnetization becomes nearly constant, and the iron seems to approach a state of magnetic saturation.

The existence of this state of saturation has been confirmed by

The general lagging of the induced magnetization behind the magnetizing force has been named by Ewing *hysteresis*. The particular curve shown in Figure 46 must be regarded merely as typical; the exact form depends on the sample of iron, and on the treatment to which it is subjected. Curves are sometimes drawn between the magnetic force  $H$  and the intensity of magnetization  $I$ . Such curves may be obtained from the curves giving the magnetic induction  $B$ , as in Figure 46, by considering the relation

$$B = H + 4\pi I.$$

From the ordinates of Figure 46, the value of  $H$  must be subtracted, and the result must be divided by  $4\pi$ , in order to get the curve of intensity of magnetization. It is also evident that the area of the closed curve in the induction diagram of Figure 46 will be  $4\pi$  times the area of the magnetization curve.

The areas of these curves have an important physical significance, which will become apparent if we consider the work done in putting a piece of iron round the cycle of changes represented in the diagram.

We may imagine that we magnetize a magnet by separating a series of very small equal and opposite quantities of magnetism at one end, and carrying one of the separated quantities along the magnet to form the other pole. If the magnet be indefinitely short compared with its breadth, or if we imagine it to be cut out of a solid block of material, the magnetic force  $H$  between its poles will be uniform, and the work done in separating the one small quantity of magnetism  $\delta m$  from the other over the length  $2l$  of the magnet is  $2lH\delta m$ .

This infinitesimal shift of magnetism involves an infinitesimal change  $\delta I$  in the intensity of magnetization. If  $\alpha$  be the area of cross section of the magnet, we have (p. 75)

$$\delta I = \delta m / \alpha.$$

Hence the work done during the process we have described is

$$2\alpha H \delta I.$$

But  $2\alpha$  is the volume of the magnet. Hence, measured in ergs, the work done per unit volume is

$$W = H \delta I.$$

By a process similar to that used on page 41, it follows that, in a magnetization curve corresponding to the induction curve in Figure 46, while the magnetization of the iron passes along the curve from  $O$  to  $P$ , the total work done, or  $\Sigma H \delta I$ , is represented by the area  $OPB$ ; while, throughout a complete cycle of changes, the excess of the work done in magnetizing over the work returned while demagnetizing, for unit volume of the iron, is represented by the area of the hysteresis loop in a magnetization diagram drawn between  $H$  and  $I$ . This work is dissipated in the iron and appears as heat.

The area of the hysteresis loops on the  $B$  and  $H$  curves is, as we have seen,  $4\pi$  times the area of the corresponding loops on the  $I$  and  $H$  curves. Hence the work done in ergs is represented by  $1/4\pi$  times the area of the  $B$  and  $H$  loops in Figure 46.

When iron is to be used in electromagnetic machinery, it is important that a knowledge of the magnetic properties of different samples should be obtained. For most purposes it is desirable that the permeability should be high and the hysteresis small.

Practical instruments have been devised, whereby the permeability may be estimated quickly by the tractive force exerted on a standard block of iron by the sample to be tested when forming the core of an electromagnet. The hysteresis effect may be determined by an instrument invented by Ewing, in which the lagging of the magnetization in the sample bar is made to exert a force on a permanent magnet, in front of which the bar revolves.

The permeability ( $\mu = B/H$ ) is not constant as the magnetic force changes, as is seen from the varying slope of the curve in different parts of the  $BH$  diagram, or from the following table of experiments on strips of steel.

$H$	$B$	$\mu$
1	1580	1580
2	4930	2465
3	7000	2333
10	11800	1180
20	13840	692

The permeability is greatest for moderate fields, where the curve rises most rapidly, and falls off rapidly as the field increases and the iron approaches saturation. At ordinary temperatures, for good soft iron, it may vary from 2000 to 4000 C.G.S. units. For small values of  $H$ , it increases considerably with the temperature, till a critical temperature of  $700^{\circ}$  to  $900^{\circ}$  is reached, when the permeability falls rapidly to unity, and the susceptibility vanishes, iron becoming a non-magnetic substance till recooled. That this is connected with the internal structure of the iron is shown by the fact that, at the same critical temperature, the phenomenon known as recalcence appears. If a piece of iron be heated above this temperature till nearly white hot and allowed to cool, it changes to a dull, almost invisible redness, and then brightly glows again as it passes the critical temperature. This behaviour probably means that a change in the crystalline structure of the iron occurs about the temperature in question—a change which involves the absorption of latent heat. As the iron loses heat it may become undercooled, just as water kept without disturbance may be cooled below its freezing-point. When the structural change sets in, it will then proceed rapidly, and a large amount of latent heat will be evolved; thus the temperature may rise considerably. It is likely that some such structural change produces the marked alteration in magnetic properties which iron displays at the temperature of recalcence. The rise of temperature is actually shown in the cooling curves given in Figure 72, § 46.

**34.** If a magnetized steel knitting-needle be broken in halves, each half will be found to act as a permanent magnet; the strength of the individual poles being then the same as the strength of the poles of the original needle. This process may be repeated as long as the fragments of iron are large enough to be broken—each fragment retains its magnetic properties. If the fragments were put together again, it is evident that the intermediate poles would neutralize each other, leaving the original poles of the whole magnet effective at the ends of the chain. Such observations and considerations have

Theories of  
magnetism.

suggested that magnetism may be an atomic or molecular property, the individual atoms or molecules, or groups of molecules, being imagined as diminutive magnets.

An explanation of the phenomena of gradual magnetization was given by Weber, who suggested that, in an unmagnetized iron bar, the axes of the individual molecular magnets lie in all sorts of irregular and arbitrary directions. As a magnetic force is applied, more and more of the molecules set so that their axes point in the same direction. Contiguous poles of the molecular magnets neutralize each other except at the ends of the bar, where the effective poles of the whole magnetic system appear.

That some rearrangement of the molecules is involved in the process of magnetization seems indicated by the changes in volume which then occur. Joule observed that the elongation of a bar of iron or soft steel on magnetization was, up to a certain point, proportional to the square of the intensity of the magnetizing force; but that it failed to comply with this relation some time before the saturation point was reached. It has since been shown that, if the magnetizing force be pushed beyond the strength with which Joule experimented, the extension of the bar ceases, and it gradually returns, first to its original length, and ultimately recedes within that limit. Cobalt, on the other hand, contracts in the early stages of magnetization and afterwards recovers its original length, and increases rapidly with increasing intensity. A bar of nickel appears to diminish in length throughout the whole process of magnetization.

In order to explain the fact that the state of magnetic saturation is not reached at once on the application of a small magnetic force, Weber supposed that the motion of the molecular magnets was opposed by a frictional resistance. But this does not explain the phenomena of residual magnetization, and Ewing showed that the supposition of friction was unnecessary as well as insufficient. Ewing suggested that a collection of little magnets, turning without friction, would, even in the absence of a magnetizing force, set themselves in stable groups under the influence of their own mutual forces. The groups will have all sorts of configura-

tions throughout the volume of the iron; the bar will possess therefore no resultant magnetic moment. On the application of a magnetic force of gradually increasing intensity, the first effect is to deflect slightly some of the magnets from their original position. This deflection will, for small angles, be proportional to the magnetic force, and, if the magnetic force be removed, the molecules will revert to their original state. These relations explain the first stage in the actual magnetization of iron—the first part of the curve in the neighbourhood of *O*, in Fig. 46.

As the magnetic force is increased, some of the groups of molecular magnets become unstable and break up. More and more of the little magnets set in the direction of the impressed force. When nearly all of them are so arranged, the iron approaches its state of saturation.

Ewing constructed a model, consisting of a number of small compass-needles pivoted and placed on a board. The board was fixed within a solenoidal coil of wire, through which an electric current could be passed. In this way a hysteresis curve was obtained—a curve which reproduced in a very striking manner the phenomena of the magnetization of iron.

The structure of the individual molecular magnets remains to be considered. As we shall see in the next chapter, an electric current flowing in a closed circuit acts as a magnet. Long ago Ampère suggested that the conception of electric currents flowing in minute circuits, round or within the individual molecules, might furnish a more fundamental explanation of magnetic phenomena. And, of recent years, this hypothesis has gained added significance. As we shall see in the sequel, Prof. J. J. Thomson sees reason to believe that the properties of atoms may be explained by the supposition of negatively electrified corpuscles, which perhaps constitute isolated electric charges, revolving in orbits within a sphere of uniform positive electrification, whatever may be the exact meaning to be attached to this expression. It has been shown experimentally, by Rowland and others, that a moving charge of electricity is equivalent to an electric current. The requirements of Ampère's hypothesis are thus satisfied by the latest theory of

the atom, though why iron should so far transcend all other known substances in magnetic properties remains a problem for future elucidation.

## CHAPTER V.

### THE ELECTRIC CURRENT.

Discovery of the electric current. Voltaic cells. Effects of the galvanic current. Relations between currents and magnets. Magnetic force inside a solenoid. Magnetic force due to a long, straight current. Ampère's hypothesis. A circular current. The tangent and ballistic galvanometers. Electromotive force. Ohm's Law. Electric Resistance. Wheatstone's bridge. Specific resistance. Comparison of electromotive forces. Heating effect of an electric current.

**35.** THE different forms of apparatus for the production of electricity, hitherto discussed, are all intended primarily to enable us to give a static charge of electricity to some insulated conducting body. It is true that, if a conducting circuit be formed, connecting the collecting apparatus of an electric machine with the rubber or with the earth, a more or less continuous flow of electricity must proceed along the circuit. Even in the most elaborate form of influence machine, however, the amount of electricity passing in a second is so small that it is difficult to detect the current in the conducting wires; though, if an air gap be interposed, the high differences of electric potential produced by the machine result in visible sparks and the attendant phenomena.

At the beginning of the nineteenth century, a new field of research was opened up by the discovery of the galvanic or voltaic cell. This arrangement gave rise to a series of phenomena grouped originally under the name of galvanism, which, by the efforts of many observers, was gradually brought into relation with

Discovery of  
the electric  
current.

the older electricity. Faraday may be said to have established finally the identity of the two manifestations. He showed that a galvanic current was nothing more nor less than a flow of electricity, enormous in quantity compared with that given by an electric machine, but driven along by potential differences many thousand times less than those involved in the older type of apparatus. Since no accumulation of electricity can be detected at any point in the circuit, it follows that the current may be represented figuratively by the flow of an incompressible fluid along rigid and inextensible pipes. We define the strength of the electric current, as we shall see later, by means of the magnetic force it produces, and therefore we must not define it by means of the quantity of electricity passing. We must reverse this procedure, and make a new definition of quantity of electricity. Unit quantity of electricity passes any cross-section of a circuit when a current of unit strength flows round that circuit for unit time. The relation of this definition of unit quantity of electricity with the statical definition based on the mechanical forces between charged bodies will be considered in a future chapter.

The discovery of the voltaic cell was due to a chance observation, which seemed at first to lead in a different direction—an experience not uncommon in the history of scientific investigation. About the year 1786, an Italian named Galvani noticed that the leg of a frog contracted under the influence of a discharge from an electric machine. Following up this discovery, he observed the same contraction when a nerve and a muscle were connected with two dissimilar metals, placed in contact with each other. Galvani attributed these effects to a so-called animal electricity, and it was left for another Italian—Volta, of Pavia—to show that the essential phenomena did not depend on the presence of an animal substance. In 1800 Volta invented the pile known by his name, which, in the opening years of the following century, provided a means of investigation yielding results of intense interest in the hands of the discoverer and his contemporary workers in other countries. The scientific journals of the time are full of the marvels of the new science, the study of which was taken up with an ardour little short of that shown a century later in the elucidation of the phenomena of radio-activity.

**36.** Volta's pile consisted of a series of little discs of zinc, copper, and paper moistened with water or brine, placed one on top of the other in the order—zinc, copper, paper, zinc, etc....finishing with copper. Such an arrangement is really a primitive primary battery, each little pair of discs separated by moistened paper acting as a cell, and giving a certain difference of electric potential, the differences due to each little cell being added together and producing a considerable difference of potential (or electromotive force as it is now called) between the zinc and copper terminals of the pile. Another arrangement was the crown of cups, consisting of a series of vessels filled with brine or dilute acid, each of which contained a plate of zinc and a plate of copper. The zinc of one cell was fastened to the copper of the next, and so on, an isolated zinc and copper plate in the first and last cell respectively forming the terminals of the battery. Volta thought that the origin of the effects was to be sought at the junctions of the two metals; hence the order of the discs in the pile and the terminal metal plates in air in the crown of cups. These plates, and the corresponding discs in the pile, were soon found to be useless, though they figure extensively in early pictures of the apparatus.

If a current be taken from Volta's pile or crown of cups, that current rapidly diminishes in intensity; this is due chiefly to a film of hydrogen which forms on the surface of the copper plate. In a later chapter we shall study the theory of such phenomena under the head of electrolytic polarization. Here we are concerned merely with the practical means adopted to eliminate its effects in voltaic cells. Cells can be classed in three groups, according as the depolarizing action is mechanical, chemical, or electrochemical. The following examples may be given:

*Cells mechanically depolarized.* Smee's cell, where a silver plate is covered with crystals of platinum, the sharp edges of which aid the escape of the hydrogen.

*Cells chemically depolarized.* 1. The bichromate battery. The zinc and carbon plates are surrounded with an oxidizing mixture of sulphuric acid and a strong solution of potassium bichromate. The hydrogen, instead of being evolved as gas, is oxidized to water.

2. The Leclanché cell, consisting of zinc in a solution of sal-ammoniac, and carbon surrounded with a mixture of broken carbon and manganese dioxide.

3. Grove's cell, where one plate is zinc in dilute sulphuric acid, and the other is platinum in strong nitric acid contained in a porous pot.

*Cells electrochemically depolarized.* 1. Daniell's cell, in which zinc is placed in dilute sulphuric acid or a solution of zinc sulphate, and a porous pot contains copper immersed in a strong solution of copper sulphate. Copper is deposited on the plate instead of hydrogen.

2. Latimer Clark's cell, used as a standard of electromotive force. Here a zinc rod is placed in a solution of zinc sulphate; and mercury is covered with a paste of mercurous sulphate, which deposits mercury when an electric transfer occurs.

37. As we have said, the discovery of the galvanic current was made by the detection of its physiological effects on the leg of a frog. As soon as the invention of the voltaic cell placed a more powerful instrument in the hands of investigators, it was found that striking chemical changes accompanied the flow of the current through water and aqueous solutions. To these phenomena the early experimenters chiefly directed their attention. A detailed study of this important branch of our science will be found in the chapter on electrolysis, and we shall now pass to other subjects.

Effects of the  
galvanic  
current.

It was soon found that, when passing through a conductor of any kind, the current evolved heat, the amount of which depended on the nature of the conductor. This thermal effect also will be considered later. In this place we shall depart from the chronological order of development, and pass to another property of the current, namely, its power of deflecting a magnetic needle. This power was discovered by Oersted of Copenhagen in 1820. Its importance for our present purpose lies in the fact that, by the magnetic force which a given current will produce, the strength or intensity of that current is, by general agreement, defined and measured. Moreover, the magnetic effects of minute currents give the most sensitive means of detecting them in metallic conductors.

By a convention universally adopted, we agree to suppose that

an electric current flows in the direction of the positive electricity, that is, from the zinc to the copper (or carbon) plate within the battery, and from the copper to the zinc along the wire outside. In accordance with this convention, the copper plate is called the positive, and the zinc plate the negative terminal of the battery.

If a wire, along which a current is passing from south to north, be placed over and parallel to a compass-needle, the north-seeking pole is deflected towards the west. If the wire be placed below the needle, with the current still passing from south to north, this deflection is reversed. Thus, if the wire be wound in a coil, so that the current passes in one direction above the needle and returns in the other direction below, the effects on the needle are of the same sign, and the deflection is multiplied greatly. Such an arrangement is known as a galvanometer. Except in special cases, the chief use of a galvanometer is to detect the presence and direction of electric currents; hence the object in designing a galvanometer is to increase the sensitiveness; it is not usually necessary to know the relation between the strength of the current and the deflection of the needle.

A very sensitive galvanometer, invented by Lord Kelvin, is shown in Figure 47. It consists of a coil of wire closely surrounding a small suspended mirror, on the back of which are fixed several pieces of magnetized watch-spring, as in the magnetometer illustrated in Figure 34 on page 66. As we have seen, the deflection of a needle produced by a magnetic force  $F$ , applied at right angles to the original position of the needle, is given by

$$F = H \tan \delta,$$

where  $H$  is the strength of the field (due to the earth or other magnetic system) in which the needle hangs. The deflection produced

Fig. 47.

by a given force, that is, by a given current, will thus be inversely proportional to  $H$ , the strength of field. The sensitiveness of the galvanometer therefore will be much increased by the use of a control steel magnet, which can be moved into such a position that it counteracts and nearly balances the earth's horizontal field of force.

The sensitiveness has been increased still further by fixing to a light rigid glass fibre two systems of light steel strips with their poles in opposite directions. The strengths of these magnets are adjusted carefully till they are nearly equal as well as opposite, and the astatic system is then suspended by a quartz fibre so that each half lies within a coil. The current flows in opposite directions in the two coils, and the deflection is read with a telescope and mirror. A current of  $10^{-10}$  ampere may thus be detected.

Since a current produces a magnetic force, it will itself experience a force when placed in a magnetic field, whether that field is due to permanent magnets or to other currents. The phenomena of attraction and repulsion between circuits of wire, freely suspended and carrying currents, were investigated experimentally by Ampère, and the deflection of coils, placed in the strong field of permanent magnets, is now extensively used in galvanometers of the moving-coil type (Fig. 49). Such instruments, while not quite so sensitive as those already described, have important advantages. One of the chief advantages of these galvanometers is their freedom from disturbance when the external field of magnetic force is liable to some amount of variation, owing to

Fig. 48.

Fig. 49.

the movement of masses of iron, etc. The field produced by the permanent magnets is so very strong, compared with that of the earth and other external objects, that a small variation in the external field is inappreciable. In the d'Arsonval galvanometer, the current is led into the coil by a phosphor-bronze strip, which also acts as a means of suspension, and is taken out by a torsionless coil of fine silver wire.

In practical ammeters and voltmeters, the moving coil is

Fig. 50.

mounted on pivots between jewels, and carries a pointer which moves over a scale divided so as to read amperes or volts directly. Fig. 50.

- 38.** The experiments of Ampère and Weber showed that coils of wire carrying currents acted in the same manner as magnets of the same size and shape, and of appropriate magnetic strength.

Relations  
between cur-  
rents and  
magnets.

A long helical coil, which is called a solenoid, will, for instance, produce an external magnetic field exactly similar to that due to a bar magnet of the same shape and dimensions as the coil, and, if balanced on two points, as shown in Figure 51, will set like a magnet in the magnetic meridian of the earth. As the length of the solenoid is decreased, the equivalent magnet becomes shorter also, and, if the coil be imagined as reduced to a single circle of wire, the equivalent magnet must be

represented by a circular disc of steel, magnetized in a direction at right angles to its plane, so that one face of the disc is a large flat north-seeking pole, and the other face a similar south-seeking one. Such a disc is known as a *magnetic shell*. A magnetic shell may be imagined as made up of a number of very minute bar-magnets placed side by side, with all the poles of one name pointing the same way.

Fig. 51.

If a small circuit be equivalent to a corresponding magnetic shell, it must follow that the same relation holds for circuits and shells of any size. A large shell may be imagined to be resolved into a number of small shells of equal strength. Each of these may be replaced by its equivalent current flowing round the edge of the little shell; and, since the currents too must be of equal strength, the currents along each internal junction line will cancel, and we are left with one continuous current flowing round the external edge of the large shell.

It will be evident that a closed electric circuit of any size and form is equivalent to a magnetic shell of the same size and form, with its edge coinciding with the wire carrying the current. This equivalence between magnets and currents extends only to the external magnetic fields which they produce. Inside the coils and magnets the conditions are different.

As we have seen in § 28, the effect of a magnet at outside points depends on a quantity known as the magnetic moment. In the case of magnetic shells, it is convenient to use a corresponding quantity which does not depend on the size or shape of the shell. Hence we define the *strength of a magnetic shell* as the magnetic moment per unit area. From the experimental equivalence between currents and magnetic shells, it follows that the

electromagnetic unit of current may be defined theoretically as that current which is equivalent to a magnetic shell of unit strength.

If two circular currents be placed parallel to each other, it is clear that, if the currents circulate in the same direction in each circuit, the equivalent magnetic shells will have poles of opposite name facing each other. Thence follows a result readily verified by experiment, namely, that currents flowing in the same direction attract each other, while currents flowing in opposite directions repel each other.

In § 30, we found that the magnetic potential of a short bar-magnet at a point at a distance  $r$  from the centre of the magnet was  $M \cos \theta / r^2$ , where  $\theta$  is the angle between the magnetic axis of the magnet and the line joining its centre to the point considered. If we imagine the magnet shortened till it becomes vanishingly short, we get a small magnetic shell, and the same expression still gives the potential at an external point.

We defined the strength  $S$  of a shell as the magnetic moment per unit area. Thus  $S$  is  $M/\alpha$ , and the potential  $V$  is given by

$$V = S \frac{\alpha \cos \theta}{r^2}.$$

Now  $\alpha \cos \theta / r^2$  measures the solid angle  $\varpi$  which the shell subtends at the point  $P$ . Hence

$$V = S\varpi.$$

For a large shell, the potential is the sum of the potentials due to the small shells of which we may suppose it to be constituted. Thus, if  $\Omega$  be the solid angle subtended by a magnetic shell of any size at an external point  $P$ , the potential at that point is equal to the strength of the shell multiplied by the solid angle which it subtends at the point, for the strength of the shell is uniform all over its surface, and

$$V = \Sigma S\varpi = S\Sigma\varpi = S\Omega.$$

Since currents are equivalent to magnetic shells, a similar expression gives the magnetic potential at a point due to a current  $c$ . If  $\Omega$  denote the solid angle subtended at the point by the circuit in which the current flows,

$$V = c\Omega,$$

unit current, in accordance with our definition, being taken as equivalent to a shell of unit strength.

Let us imagine a circuit of wire of any form through which passes a current  $c$ . Its magnetic effect on points outside it will be the same as that of the equivalent magnetic shell. At a point indefinitely near the plane of the shell, the solid angle which the shell subtends is half that of the whole surrounding sphere, or  $2\pi$ . The potential at that point due to the equivalent current is therefore  $2\pi c$ . At a corresponding point on the opposite side of the plane of the shell or current the solid angle is  $-2\pi$ , and the potential is  $-2\pi c$ . Thus the difference of potential between these two points is  $4\pi c$ .

The difference of magnetic potential between two points is defined as the work done against the magnetic forces in carrying a unit north-seeking magnetic pole from one to the other. Thus, if we take a unit north-seeking magnetic pole from a point just outside the plane of a shell or current to a corresponding point on the other side, the path being in air round the edge of the shell or current, the work done is  $4\pi c$ .

To pass through the shell, and regain the original point, we must suppose the pole taken up through a hole in the shell. Here the work is clearly reversed, and, when we regain the original point, the total work done vanishes, as, indeed, follows from the principle of the conservation of energy. But here appears a difference between currents and shells. In completing the path round the current, there is no steel to pass. The path is completed through air, and there is clearly no discontinuity of force. Thus the work done in taking a unit north-seeking magnetic pole completely round from one side of the current to the other is not appreciably added to by taking it through the indefinitely short path required to complete the circuit and return to the original point: the total work is still  $4\pi c$ .

This difference between magnets and currents is significant. It depends on the fact that in the current we have a source of energy maintained elsewhere, from which we may draw when moving a magnetic pole in the neighbourhood. In a magnet we have no such source of energy, and no work can be gained or lost by moving a pole so that in the end it returns to its

starting-point. The equivalence between shells and currents does not hold when we deal with points within them—it applies to external points alone. But, it will be noticed that the magnetic force due to the current is everywhere equivalent to the magnetic induction due to the shell; magnetic force is continuous in air, but magnetic induction is continuous in any field, simple or complex, magnetic or non-magnetic.

If we suppose that the two points on opposite sides of the plane of the current lie very near one edge, the work done against the magnetic forces must be due entirely to that portion of the current in the neighbourhood. Thus, whenever a unit north-seeking magnetic pole is made to circulate once round a current  $c$ , work to the amount of  $4\pi c$  is done.

Fig. 52.

39. An application of this result enables us to deduce the value of the magnetic field inside a solenoid, that is, a helical coil of wire through which passes a current.

Magnetic  
force inside  
a solenoid.

Let us imagine that an isolated magnetic pole of unit strength is carried along a path  $AB$  inside and parallel to the axis of a portion of a very long solenoid (Fig. 53). Let the pole be then brought out between the wires of the coil, taken outside along the path  $DE$ , and returned to the inside of the coil between the wires along the path  $EA$ . By § 38, the work done is  $4\pi c$  for each turn of wire surrounded by the path, and, if  $n$  be the number of turns of wire per unit length of the coil, the total work done is  $4\pi nc \cdot \overline{AB}$ .

Fig. 53.

The lines of force of the solenoid will be similar to those of a bar-magnet, except that, instead of ending on the poles, they form continuous curves by running back along the inside of the coil. Thus, inside the coil, all the lines of force are crowded into a small space, but outside, the same number are spread throughout the

whole field. If the coil be very long, then the number of lines in the region  $DE$  is vanishingly small compared with the number inside the coil. Along  $DE$  the force is negligible, and the work done when the pole is taken along it is negligible also. The portions  $BD$  and  $EA$  of the paths run at right angles to the lines of force, and, along them also, the force vanishes, and no work is done. The whole of the work throughout the path is concentrated into the length  $AB$ , and, throughout that length, the magnetic force is, by symmetry, uniform. Writing this magnetic force as  $H$ , the work is  $H \cdot \overline{AB}$  and

$$H \cdot \overline{AB} = 4\pi nc \cdot \overline{AB}.$$

Thus

$$H = 4\pi nc.$$

Nothing has been said about the distance of the line  $AB$  from the axis of the coil, and the result holds for all places inside the solenoid. The field of force, then, is uniform everywhere inside the solenoid, and acts in the direction parallel to the axis.

This result has been used already in describing the experimental method of determining the magnetization of iron, and is of great importance in the theory and manufacture of electromagnetic machinery.

#### 40. The expression $4\pi c$ for the work done in carrying a unit pole

Magnetic force  
due to a long,  
straight cur-  
rent. Ampère's  
hypothesis.

round a current enables us also to calculate the force due to a long, straight current. Since the magnetic force of the equivalent shell must act normally to the surface, it follows that the lines of force due to

the current are circles surrounding the wire with their planes at right angles to its length. These circular lines of force may be mapped out by a compass-needle, or by sprinkling iron filings over a card threaded by the wire. By carrying a unit magnetic pole round the wire once, an amount of work equal to  $4\pi c$  is done. The length of path of the pole is  $2\pi r$ , where  $r$  is the radius of its orbit. The force is uniform over such a circular orbit by symmetry, and the magnetic

Fig. 54.

force, which is defined as the force on a unit north-seeking magnetic pole, at a distance  $r$  from the wire, is given by

$$H = \frac{4\pi c}{2\pi r} = \frac{2c}{r}.$$

It was shown by Ampère that the magnetic effects of complete currents were the same as though each element of length  $\delta l$  of the current produced its own magnetic force at a point equal to  $c\delta l \sin \theta / r^2$ , where  $\theta$  is the angle made by the elementary length with the line joining it to the point at a distance  $r$ . The conception of an isolated length of current is not in accordance with modern views of the electric current, which is now regarded as essentially a flow round a complete circuit. Mr Heaviside, however, has evaded this difficulty by the conception of what he calls the “rational current element.”

Let us imagine that a circuit is formed of a short straight element of current  $\delta l$ , and of lines of current-flow in the surrounding space; the lines being those mapped out by the lines of magnetic induction of a short bar-magnet. The current all passes along the element  $\delta l$  in one direction, and returns by many paths spreading through the neighbourhood to form a closed circuit. This system constitutes Heaviside’s rational current element. We must trace two properties of such elements:

(1) If two elements be placed together, the lines of current flow which formerly diverged from each end of one element will now pass along the second element before diverging, just as do the lines of induction if two short magnets be placed together to form a longer one. And, as a long magnet may be made up of any number of short ones, all poles disappearing except those at the ends, so current elements may be joined together, and all the lines of flow will pass through the elements in series before diverging from the ends of the chain. If we carry this process to its conclusion, and form a closed ring of current elements, all current will flow round the ring, and none will spread through the surrounding space—we have, in fact, the analogue of a complete ring of iron, when the lines of induction circulate round the ring and never leave the iron. We see, then, that a closed chain of rational current elements forms a closed circuit of the kind actually known

in practice, when all the current flows within the circuit, and none spreads through the neighbouring medium.

(2) The second important property of the rational current element is the production of a magnetic force in accordance with Ampère's formula. Let  $AB$  (Fig. 55) be the short length of the current element. Lines of return flow spread out from  $A$  and converge again to  $B$ . These lines are, by hypothesis, coincident with the lines of induction given by a short magnet lying at  $AB$ .

Fig. 55.

With its centre at  $O$ , a point on the axis of  $AB$  produced, describe a circle, the plane of the circle being normal to the axis of  $AB$ . Let us calculate the total magnetic induction through this circle due to a magnet at  $AB$ . The number of lines of induction through  $AB$  is equal to  $c$  the strength of current, and from each end of the element  $AB$ , the lines diverge uniformly. The number which threads the circle round  $O$  is measured by  $c/4\pi$  per unit solid angle,  $4\pi$  being the measure of the solid angle which a complete sphere subtends at its centre. If  $\omega_A$  and  $\omega_B$  denote the solid angles subtended by the circle at  $A$  and  $B$  respectively, the total induction through the circle is

$$\frac{c}{4\pi}(\omega_A - \omega_B),$$

and, by analogy, this denotes also the amount of current passing through the circle when the hypothetical magnet is replaced by the hypothetical rational current element.

Now join  $A$  and  $B$  to any point  $P$  on the circumference of the circle, and parallel to  $BP$  draw  $AQ$  to meet the radius  $OP$  of the circle in  $Q$ . Draw  $QK$  perpendicular to  $AP$ . The quantity  $\omega_A - \omega_B$  is the solid angle subtended at  $A$  by the annular ring described by the revolution of  $PQ$  round the circle, and this solid

angle is sensibly equal to that subtended by the ring described by  $QK$ . Hence

$$\omega_A - \omega_B = 2\pi \cdot OP \frac{QK}{r^2},$$

where  $r$  denotes the distance  $AQ$ , which is sensibly equal to  $AP$ . Draw  $AN$  perpendicular to  $BP$ ; we then have

$$\begin{aligned}\omega_A - \omega_B &= 2\pi \cdot OP \frac{AN}{r^2} \\ &= 2\pi \cdot OP \frac{\delta l \sin \theta}{r^2},\end{aligned}$$

where  $\theta$  is the angle between  $AB$  and  $BP$ , and  $\delta l$  is written for the element of length  $AB$ .

We are now in a position to calculate the magnetic force  $H$  at the point  $P$  due to the rational current element. By symmetry, the lines of magnetic force due to the current must coincide with the circumference of the circle  $OP$ , and we know that the work done in taking a unit magnetic pole round that circle is measured (1) by  $2\pi \cdot OP \cdot H$  and (2) by  $4\pi$  times the current enclosed by the path. Thus, we get the equation

$$2\pi \cdot OP \cdot H = 4\pi \left( \frac{c}{4\pi} 2\pi OP \frac{\delta l \sin \theta}{r^2} \right),$$

or

$$H = \frac{c \delta l \sin \theta}{r^2},$$

in accordance with Ampère's formula.

By the two properties (1) and (2) of Heaviside's rational current element, we have justified the use of Ampère's formula in calculating the magnetic forces due to complete current circuits of any size and shape. The resultant magnetic force of any circuit is equal to the sum of the forces due to its individual rational current elements.

We may therefore use Ampère's formula to calculate the magnetic effects of different currents, whether those currents be continuous ones carried in conductors, or the flights of charged particles which have become recently of so much importance.

Ampère's formula may also be applied to calculate the mechanical forces between circuits, or circuits and magnets. The magnetic

force due to the current element being  $c\delta l \sin \theta / r^2$ , and that due to a magnetic pole of strength  $m$  being  $m/r^2$ , it follows from the principle of equivalence between currents and magnets that  $c\delta l \sin \theta$  is equivalent to  $m$ . Now if a pole  $m$  be placed in a magnetic field where the induction is  $B$ , the mechanical force on it is  $Bm$ . Thus on the current element the mechanical force is  $Bc\delta l \sin \theta$ , the direction of the force being at right angles both to the current and to the lines of induction, and  $\theta$  denoting the angle between the lines of induction and the direction of the current.

Fig. 56.

A long straight current produces at a distance  $r$  a magnetic force  $2c/r$ . If a second long straight current  $c'$  be brought near and parallel to the first, the mechanical force on a length  $l$  must be  $2cc'l/r$ . Since this force acts at right angles both to the current and to the induction, it is a direct force of attraction between the currents if they flow in the same direction, and a direct repulsion if they flow in opposite directions.

**41.** For a circle of wire carrying a current  $c$ , Ampère's formula for the magnetic force due to an element of current leads to a very simple result. The distance from the centre is everywhere uniformly  $r$ , and  $\sin \theta$  is everywhere unity. For each element of current the magnetic force at the centre of the circle is therefore  $c\delta l/r^2$ , and, for the whole circumference,

$$\frac{2\pi cr}{r^2} = \frac{2\pi c}{r}.$$

This result gives a convenient means of putting our definition of unit current (p. 98) into a more practical form. Unit current is evidently that current which, when flowing in a circle of radius  $r$ , produces at the centre a magnetic force of  $2\pi/r$ .

The importance of this result makes it desirable that the magnetic force at the centre of a circular current should also be

derived directly from the idea of the equivalence of currents and shells, without the use of Ampère's hypothesis.

Let  $AB$  represent a circular current, and  $O$  its centre. We will calculate the magnetic force at  $P$ , a point on the axis of the circle. The magnetic potential at  $P$  is by § 38 equal to  $c\Omega$ , where  $c$  is the current in electromagnetic units, equivalent to the units of strength of magnetic shell, and  $\Omega$  the solid angle subtended at the point by the circle.

Fig. 57.

The solid angle is measured by the area of the spherical cap, drawn through  $AB$  with  $P$  as centre, divided by the square of the distance  $AP$ . The area of the cap is equal to that of a cylindrical ring of equal depth, cut from the cylinder which touches the sphere, of which the cap forms part, by two parallel planes, one containing the circle  $AB$ , and the other touching the top of the cap at  $Q$ , a point on  $PO$  produced. Thus, the area of the cap is  $2\pi \overline{AP} \cdot \overline{OQ}$ , and the solid angle which it subtends at  $P$  is  $2\pi \overline{AP} \cdot \overline{OQ} / \overline{AP}^2$ .

The magnetic potential at the point  $P$  is given by the relation

$$V = 2\pi c \frac{\overline{AP} \cdot \overline{OQ}}{\overline{AP}^2}.$$

Thus, if we denote the distance  $OP$  by  $x$ , and  $OA$ , the radius of the current, by  $r$ , we have

$$\begin{aligned} V &= 2\pi c \frac{\overline{AP} (\overline{AP} - x)}{\overline{AP}^2} \\ &= 2\pi c \left\{ 1 - \frac{x}{(r^2 + x^2)^{\frac{1}{2}}} \right\}. \end{aligned}$$

Now the magnetic force  $F$  in any direction  $x$  is, by the definition of potential (§ 8), equal to the rate of decrease of the magnetic potential per unit distance in that direction, or  $-dV/dx$ . Thus,

$$\begin{aligned} F &= -\frac{dV}{dx} \\ &= 2\pi c \frac{r^2}{(r^2 + x^2)^{\frac{3}{2}}}, \end{aligned}$$

and this result gives us the magnetic force at any point on the axis of a circular current. It may also be derived directly from Ampère's formula. We can find the magnetic force at the centre  $O$  by putting  $x = 0$ , when

$$F = \frac{2\pi c}{r},$$

in accordance with our previous result.

If the current be made to pass  $n$  times round the circle, the force will be  $n$  times as great; the magnetic force at the centre of a coil of  $n$  turns of wire is given by

$$F = \frac{2\pi nc}{r}.$$

The mechanical force between two circular currents requires mathematical analysis, except in simple cases. One such case consists of two circles of equal radius  $r$ , placed parallel with a distance  $d$  between their planes,  $d$  being very small compared with  $r$ . We may then apply our result on page 105 for two long parallel currents, and obtain at once the expression  $4\pi rcc'/d$  for the mechanical force between the two circles,  $c$  and  $c'$  being the respective currents.

42. We are now in a position to measure a current of electricity in absolute electromagnetic units, and it will be useful to consider exactly the meaning of such a measurement.

The tangent  
and ballistic  
galvano-  
meters.

The proportionality between a current and the magnetic force it produces is a matter of definition. We do not *prove* that the magnetic force is proportional to the current, but we agree to *define* the strength of a current as the strength of the hypothetical magnetic shell, which may be imagined to replace the current, and to produce the same magnetic field. Then, in one of the two ways we have given, we calculate the magnetic force of the shell which is equivalent to a current flowing in a circular coil of wire.

We may now suspend a compass needle at the centre of such a coil, and place the plane of the coil in the magnetic meridian, so that the needle lies in that plane when no current passes. If the coil is large and the needle short, its ends will never be far from the centre of the coil, and the needle may be considered to lie in a uniform magnetic field, the direction of which is normal to the magnetic meridian and the plane of the coil. For convenience in observing, a light and long pointer is fixed to the needle at right angles to its length, or a mirror arrangement may be used. In accordance with the principles described on p. 64, the needle will be deflected by this magnetic field  $F$  through an angle  $\theta$ , which is given by the relation

Fig. 58.

$$F = H \tan \theta,$$

$H$  being the horizontal component of the earth's magnetic force.

Thus, if a current  $c$  flow round  $n$  turns of wire arranged in a large circular coil of radius  $r$ , we have

$$\frac{2\pi nc}{r} = H \tan \theta,$$

or

$$c = \frac{Hr \tan \theta}{2\pi n}.$$

For accurate work, it is necessary to take account of the fact that all the turns of wire do not lie in a single circle. For rough work,  $r$  may be put equal to the mean radius of the coil.

The quantity  $2\pi n/r$  depends only on the dimensions of the galvanometer, and, if we call this quantity the galvanometer-constant and denote it by  $G$ , we get

$$c = \frac{1}{G} H \tan \theta.$$

If we keep the instrument always fixed in one position in the laboratory, and no masses of iron are moved in the neighbourhood,

the local value of  $H$  can be found once for all, and we may write all the constants of our equation as a single *reduction factor*  $k$ , and obtain the useful formula

$$c = k \tan \theta.$$

It is interesting to calculate the percentage error involved in assuming, as we have done, that the needle lies in a uniform magnetic field.

A small pattern tangent galvanometer is often seen in elementary laboratories. The diameter of the coil is about 20 centimetres, and the length of the needle about 2 centimetres. If in such a case the needle were deflected through  $90^\circ$ , its ends would lie each 1 centimetre from the centre of the coil.

At a point on the axis of a circular coil, at a distance  $x$  from the centre, we have seen (p. 106) that the magnetic force is  $2\pi cr^2/(r^2 + x^2)^{3/2}$ , while at the centre it is  $2\pi c/r$ .

Now  $r^2/(r^2 + x^2)^{3/2}$ , in this case, is equal to  $100/(101)^{3/2}$  or about  $100/1015$ , while  $1/r$  is  $1/10$ . Thus the percentage difference is about 1.5, and we see that, with the rough instrument we have described, results accurate to about one and a half per cent. should be obtained if the coils may be assumed to lie in a single circle.

The accuracy can of course be increased by using larger coils or shorter needles. Still more exact results can be obtained by placing two or three coils parallel to each other so that the coils lie on the surface of a sphere at the centre of which the needle is suspended.

The tangent galvanometer gives us our first practical means of measuring a current in absolute, electromagnetic units. As a practical unit, a current equal to one-tenth of the electromagnetic unit is chosen, and called the ampere.

It is sometimes necessary to measure, not the strength of a steady current, but the whole quantity of electricity which passes during the time of flow of a transient current, such as is obtained by the discharge of a condenser, or by electromagnetic induction. A galvanometer adapted for this purpose must have a small needle, so that it lies in a uniform field of force. The moment of inertia of the suspended system must be high, and the time of swing great, so that all the current has passed before the needle has

moved appreciably from its position of equilibrium. An impulse is thus given to the needle, and, by the usual mirror arrangement, the extreme limit of its first swing or throw may be observed. The instrument is called a ballistic galvanometer, and the following investigation gives the theory of its action.

Let  $ACB$  be the position of equilibrium of the magnet, and  $A'CB'$  the limit of its swing through an angle  $\beta$  (Fig. 59). Draw  $A'D$ ,  $B'E$  at right angles to  $ACB$ . Then the lengths  $AD$  and  $BE$  represent the equal distances through which the poles of the needle are moved against the direction of the horizontal magnetic force  $H$  of the earth. If  $m$  and  $-m$  are the pole strengths, the work done is  $2mH \cdot AD$ . But if  $l$  be the half length of the needle,

$$AD = CA - CD = l(1 - \cos \beta),$$

and the work done by the earth's field in stopping the swing is

$$2mHl(1 - \cos \beta) = MH(1 - \cos \beta),$$

where  $M$  is the magnetic moment of the needle. This work must be equal to the kinetic energy of the needle at starting on its swing, i.e. to  $\frac{1}{2}K\omega^2$ , where  $K$  is the moment of inertia, and  $\omega$  the initial angular velocity. Hence

$$\omega = \sqrt{\left\{ \frac{2MH(1 - \cos \beta)}{K} \right\}}.$$

Now the moment of the force produced on the needle by the action of the current  $c$  is  $MGc$ , where  $G$  is the galvanometer constant, and, if the current last for a time  $\delta t$ , the impulse is  $MGc\delta t$ . For the whole time of flow of the transient current, the total impulse is then  $MG\int c dt$ . Now  $c\delta t$  is the amount of electricity passing during the time  $\delta t$ , and  $\int c dt$  is the total amount  $q$  of electricity passing through the galvanometer. Thus the impulse on the needle is  $MGq$ , and this must be equal to the moment of momentum  $K\omega$  of the needle. Hence  $\omega$  is equal to  $MGq/K$ .

We now have

$$\frac{MGq}{K} = \sqrt{\left\{ \frac{2MH(1 - \cos \beta)}{K} \right\}},$$

Fig. 59.

and thus

$$q = \frac{2 \sin \frac{1}{2}\beta}{G} \sqrt{\left(\frac{HK}{M}\right)}.$$

If there be no appreciable friction on the needle, and consequently no appreciable damping of the swing, the period  $T$  of one complete oscillation is

$$T = 2\pi \sqrt{\frac{K}{MH}}.$$

Hence, substituting for  $K/M$  in the equation for  $q$  we get

$$q = \frac{HT}{G\pi} \sin \frac{1}{2}\beta.$$

If the damping be appreciable, the complete mathematical investigation shows that

$$q = \frac{HT}{G\pi} \left(1 + \frac{\lambda}{2}\right) \sin \frac{1}{2}\beta,$$

where  $\lambda$  is the so-called logarithmic decrement, that is, the natural logarithm of the ratio of the amplitudes of successive swings.

**43.** In dealing with the phenomena of electrostatics, we had occasion to introduce the conception of electric potential, and we defined the difference of potential between two points as the work done against the electric forces when unit quantity of electricity was carried from one point to the other.

When an electric current flows along a wire, we conceive that electricity is passing, and thus the two points along the wire must be maintained by some means at a permanent difference of potential. We may, if we please, consider the maintenance of this potential-difference as the function of the electric battery or other source of current.

In the science of current-electricity, it is usual to call a difference of potential an *electromotive force*. The name is not a happy one, for an electric force  $f$  should have the physical dimensions [force/quantity of electricity], and be related to potential-difference  $V$ , or [work/quantity of electricity], by the equation

$$f = -dV/dx.$$

The use of the name, however, is established firmly, and the convention will be accepted in this book.

The electromotive force between two points in a circuit, then, is defined as the work done against the electric forces when one electromagnetic unit of electricity passes from one point to the other.

To connect the electromotive force with the current, another definition is needed. On the conception of a current by which we regard it as analogous to the flow of an incompressible fluid, in § 35, we have already defined the electromagnetic quantity of electricity as that quantity which we must suppose to pass each cross-section of a circuit when unit current flows round the circuit for unit time. Thus it follows that our definition of the electromotive force between two points is equivalent to saying that the electromotive force is represented by the work done against the electric forces when unit current passes between the two points for unit time.

On the system of units based on the centimetre, gramme and second (C.G.S. system) the unit of work is the erg. The unit electromotive force, then, is the difference of potential which exists between two points if one erg of work is done when one electromagnetic unit of current flows between the points for one second. We shall consider the experimental determination of this unit in the sequel. It will be found to be inconveniently small for ordinary purposes, and a practical unit called a *volt*, which is  $10^8$  absolute or electromagnetic units, is employed.

Differences of potential, or electromotive forces, can be compared by electrostatic means. If the potential differences are great, they may be demonstrated by a gold-leaf electroscope, and even the small electromotive force of a voltaic cell may be measured fairly accurately in arbitrary units by means of a quadrant electrometer.

The electromotive force of a cell as thus measured will be found to depend on the materials and nature of the cell only, not on the dimensions of the plates or the amount of liquid used. If several cells be joined together in series, with the zinc plate of one cell clamped to the copper of the next and so on, the plates clamped together must be at the same potential. Thus, if the negative terminal of the first cell be joined with the earth, and

taken as at zero potential, the negative pole of the second cell must be at the potential of the positive pole of the first, that is, at a potential  $e$ , where  $e$  is the effective electromotive force of each cell. The difference of potential between the plates of each cell being the same, in passing from the negative to the positive pole of the second cell the potential again rises by  $e$ , and the potential of the positive pole of the second cell is  $2e$ . Similarly, if  $n$  cells be joined together in series, the potential of the positive terminal of the  $n$ th cell is  $ne$ , and this is the value of  $E$  the effective electromotive force of the battery of cells. The conclusion may be confirmed by experiments with a quadrant electrometer. We now see that, by increasing the number of cells in series, any required electromotive force may be applied to a given circuit.

44. The first to introduce exact ideas on this subject was

Ohm's Law.  
Electric  
resistance.

Dr G. S. Ohm, who in 1827 replaced the prevalent vague notions of "quantity" and "intensity" by the definite conceptions of current-strength and electro-

motive force. He also stated the law called by his name, which expresses the experimental result that the current-strength between two points of a circuit is directly proportional to the applied electromotive force. Ohm verified his ideas by experiments with voltaic cells and thermoelectric piles (see § 52), and found that, along a homogeneous linear conductor, the rate of fall of potential is constant.

Ohm's law, that the current  $c$  varies as the applied electromotive force  $E$ , may be stated in the form

$$c = kE,$$

where  $k$  is a constant known as the conductivity of the conductor. Another mode of statement, more usually adopted, is to say that

$$c = \frac{1}{R} E,$$

or

$$E = Rc,$$

where  $R$  is a constant which, like the conductivity, depends only on the nature, dimensions and temperature of the conductor. This constant  $R$  is called the resistance.

Lightning is well known to melt conductors which it strikes, and these effects were imitated on the small scale by the sparks from electric machines by Franklin and others. At an early date in the history of current electricity, it was noted that heat was developed in wires connected with the two poles of voltaic batteries, and in 1821 Sir Humphry Davy described to the Royal Society experiments which showed that the amount of heat liberated varied greatly with the nature of the metal. The development of heat was referred to the resistance offered by the wire to the passage of the current, and the relative amounts of heat produced by the same current in different conductors were taken as inversely proportional to their relative conducting powers. In 1826 similar experiments were made by Sir W. Snow Harris with discharges of statical electricity obtained from a battery of Leyden Jars.

The definite conceptions of current and electromotive force introduced by Ohm, led to an equally definite idea of electric resistance, as a constant depending only on the nature, dimensions and temperature of the conductor. It became possible to compare two resistances by applying to them the same electromotive force, and measuring the relative strengths of the resulting currents.

The unit of resistance is evidently to be defined as the resistance through which unit electromotive force will maintain unit current. If electromagnetic units of current and electromotive force be used, the electromagnetic unit of resistance follows. With practical units, through unit resistance, one volt will maintain a current of one ampere. This resistance is called the ohm, and is  $10^9$  absolute electromagnetic units.

With the limit of accuracy at present possible, the ohm has been found to be equivalent to the resistance of a column of mercury of 1 square millimetre in cross section and 106·3 centimetres in length, the temperature being that of melting ice.

This conducting system is easily reproduced, and, for convenience, a practical definition of the international ohm has been adopted on these lines. To avoid certain difficulties of measurement, the definition runs thus:—A column of mercury of uniform cross section, 106·3 centimetres in length, and of mass 14·4521 grammes, at the temperature of melting ice, has a resistance of one ohm.

Even should increased accuracy of experiment show differences between the true theoretical ohm and this definition, it is probable that the definition will still be kept as describing the practical unit.

Standard coils of one or more ohms are now made, and their error determined by the Board of Trade or the National Physical Laboratory. Figure 60 shows a good form of standard ohm coil. The wire is bare, and made of a platinum-silver alloy. It is wound on a mica frame, and immersed in an insulating

Fig. 60.

oil, of which the temperature is observed with a thermometer. This arrangement insures the coil being at the indicated temperature, and, in this respect, is much better than the more common method of coating resistance coils with silk, paraffin or other solid insulator, which are bad thermal conductors. The leads connected with the ends of the coil are made of thick copper bars, which may be joined to an electric circuit by means of mercury cups or, still better, cups filled with fusible alloy.

The conception of electric current as a continuous flow of electricity through the substance of the conductor, combined with the experimental relation known as Ohm's law, enables us to predict the resistances of systems of two or more conductors arranged in different ways.

If a series of conductors,  $AB$ ,  $CD$ ,  $EF$ , ... (Fig. 61) be connected together in series, the end  $B$  of  $AB$  will be at the same potential as the end  $C$  of  $CD$  clamped to it, and similarly with the ends  $D$

Fig. 61.

and  $E$ , etc., provided, always, that the conductors are made of the same material. The current  $c$  must, since no accumulation of electricity occurs, be the same throughout the series of conductors, and, if  $E_1, E_2, \dots$  be the potential-differences between the ends of the different conductors, and  $r_1, r_2, \dots$  their respective resistances,

$$c = \frac{E_1}{r_1} = \frac{E_2}{r_2} = \dots$$

Considering the whole series as one conductor, with a resistance  $R$  and a potential difference of  $E$ , equal to the sum of the potential differences  $E_1, E_2, \dots$  etc., between its ends, we have also

$$c = \frac{E}{R}.$$

Now  $E = E_1 + E_2 + E_3 + \dots$

Thus  $cR = cr_1 + cr_2 + cr_3 + \dots,$

or  $R = r_1 + r_2 + r_3 + \dots$

Another important case occurs when the conductors have all their beginnings connected together and all their ends connected together, as in Fig. 62. With this arrangement, the conductors are said to be in parallel or multiple arc. The current  $c$  flowing in at  $A$  must, by our principle, be the sum of the currents  $c_1, c_2, \dots$  in the branches  $C, D, \dots$ . The difference of potential  $E$  between the ends of each branch is obviously the same. We have

Fig. 62.

$$c = c_1 + c_2 + c_3 + \dots$$

$$= E \left( \frac{1}{r_1} + \frac{1}{r_2} + \frac{1}{r_3} + \dots \right).$$

Considering the whole system between  $A$  and  $B$ , we have

$$c = \frac{E}{R}.$$

Thus 
$$\frac{1}{R} = \frac{1}{r_1} + \frac{1}{r_2} + \frac{1}{r_3} + \dots$$

The reciprocal of the resistance of a conductor may be called its conductivity, and we may express our last result by saying that the conductivity of a series of conductors arranged in parallel is the sum of their individual conductivities.

These results for conductors in series and parallel may be verified experimentally, and thus a confirmation be obtained of Ohm's law and of the justness of the conception of the current as analogous to the flow of an incompressible fluid through the conductors.

By measuring the resistances of wires of different diameters but of the same material, it is found that, with direct continuous currents, the resistance of a wire varies inversely as its area of cross section. This follows also theoretically if we imagine the wires first arranged in parallel and then to coalesce. It follows that the current flows through the substance of the conductor and not over its surface. This result, however, does not hold for rapidly alternating currents.

The principles of continuous current-flow which we have now established may conveniently be applied to complex circuits and networks of conductors in the form of two statements known as Kirchhoff's laws.

1. The algebraical sum of the currents which meet at any point is zero.
2. In any closed circuit the algebraical sum of the products of the current and resistance in each of the conductors in the circuit is equal to the electromotive force in the circuit.

The first of these laws expresses the result that there is no accumulation of electricity anywhere in the circuit, the second follows from Ohm's law as applied to each complete circuit to be found throughout the network.

**45.** A very exact method of applying Ohm's law to the comparison of resistances was introduced by Christie and Wheatstone about 1843. The apparatus is known as Wheatstone's bridge.

Wheatstone's  
bridge.

The circuit of a voltaic cell (Fig. 63) is made to branch at  $A$  into two arms  $ACB$  and  $ADB$ , which rejoin each other at  $B$ . Let the current flow from  $A$  to  $B$ , so that the potential  $V_A$  at the point  $A$  is higher than the potential  $V_B$  at the point  $B$ .

Fig. 63.

As we pass along the arm  $ACB$ , the potential falls from  $V_A$  to  $V_B$ , and the potential  $V_C$  at  $C$  must have some value intermediate between  $V_A$  and  $V_B$ . But, along the lower arm  $ADB$  the same fall of potential occurs, so that there must be some point  $D$  in the lower arm which has the same potential as the point  $C$  in the upper arm.

If one terminal of a galvanometer be connected with  $C$ , and the wire from its other terminal be moved along  $ADB$  till it comes to  $D$ , the terminals will then be at the same potential, and no current will flow through the galvanometer. When this is the case, then, we know that  $V_C$  is equal to  $V_D$ .

When no current flows along the cross connexion  $CD$ , the current  $c_1$  in the arm  $AC$  must all pass out along the arm  $CB$ , and the currents in these arms be the same. The current  $c_2$  in the arm  $AD$  must be equal to the current in the arm  $DB$ .

Let  $P$ ,  $Q$ ,  $R$ , and  $S$  denote the resistances of the four conductors  $AC$ ,  $CB$ ,  $AD$ , and  $DB$  respectively. Then, by Ohm's law, we know that, for each conductor, the electromotive force is equal to the product of the current and the resistance, and we get the relations

$$V_A - V_C = Pc_1, \text{ and } V_C - V_B = Qc_1,$$

or 
$$\frac{V_A - V_C}{V_C - V_B} = \frac{P}{Q}.$$

Similarly 
$$\frac{V_A - V_D}{V_D - V_B} = \frac{R}{S},$$

and, since  $V_C = V_D$  when no current passes through the galvanometer, we have

$$\frac{P}{Q} = \frac{R}{S}.$$

Thus, if we know  $S$  and the ratio  $P/Q$ , we can calculate the value of the resistance  $R$ . If  $S$  be constituted to be a definite number of ohms,  $R$  is known in ohms also.

The practical application of these principles is effected in one of two ways. In the wire bridge, a long thin uniform wire, preferably of platinum-silver or some similar alloy, is stretched alongside a scale, as shown in Figure 64. The ends of this wire are soldered to thick copper bars of negligible resistance, and a coil of known resistance is inserted in the gap in the bar at  $R$ . The coil to be compared with  $R$  is inserted in the gap  $S$ . A galvanometer is connected with the screw  $D$ , between  $R$  and  $S$ , and with a travelling jockey, which, by the pressure of a key,

Fig. 64.

makes sharp contact with the wire at  $C$ . The position of the jockey is varied till, on pressing the key, no current flows through the galvanometer. When this is the case,  $S$  is given by the quantity  $RQ/P$ . It is easy to show that the sensitiveness of this arrangement is greatest when  $R$  and  $S$  are equal, and the jockey consequently near the middle of the bridge wire. Thus, a coil should be selected for insertion in  $R$  of approximately the same resistance as the coil to be compared with it.

For the second type of measurement, an arrangement of coils known as a resistance box is required. The brass blocks  $A$  and  $B$  in Figure 65 are connected inside the box through a coil of wire of known resistance. The coil is doubled on itself and wound on an insulating

Fig. 65.

bobbin in this way in order to avoid the effects of self-induction (§ 55). The resistance of the coil may be cut out of the circuit by inserting a brass plug as shown between *A* and *B*. With a series of such coils any required resistance can be thrown into or taken out of the circuit.

One arrangement of coils, sometimes known as a Post-office box, is shown in Fig. 66. Plugs are taken out of *P* and *Q* so as to

Fig. 66.

give a convenient ratio, and *S* is then adjusted till the bridge is balanced, when *R* can be calculated. By making the ratio of *Q* to *P* equal to 10 to 1, a single ohm coil in *S* is equivalent to 0.1 of an ohm in *R*. Thus fractions of an ohm may be measured.

A second, and in some ways, more convenient arrangement of coils is the dial box, shown in Figure 67. The ratio arms are

Fig. 67.

similar to those of the Post-office box, but the arm *S* is made up of coils placed in groups of units, tens, hundreds, and thousands. In the unit dial, single ohm coils join the sectors marked 1, 2, 3,

etc. to each other in series. By inserting the plug opposite 3, for instance, three ohm coils are put between the central brass core of the dial, and the zero sector, which forms the other terminal. Any resistance up to 9999 ohms can be taken out of the arm *S* by changing the position of the four plugs in the dials.

A modification of the wire-bridge arrangement, due to Professor

Carey Foster, enables us to find the difference in resistance between two coils with extreme accuracy. A stretched wire (Fig. 68) is soldered to copper bars as in the usual form of bridge, but, instead of two gaps in the bars, there are four. In the two middle ones, on each side of the galvanometer connexions, are placed two equal

Fig. 68.

coils *E*, *E'*, kept in the same conditions and at the same temperature. In the two outer gaps, beyond the battery connexions, are placed the two coils the difference of which is required; let us call their resistances *X* and *Y*. Let us adjust the jockey along the wire till the bridge is balanced. Let the length of wire to the left of the jockey then be such that its resistance is *x*. Now suppose that we interchange the two coils *X* and *Y*, and find a new position of balance for the jockey, such that the resistance of the wire to the left of the jockey is *y*. The two equal arms, which form one pair of arms for the bridge, being unchanged, the resistances of the other two arms of the bridge must be unchanged also, and thus the new arm to the left, namely *Y* + *y*, must be identical with the old arm in the same position, namely *X* + *x*. Thus

$$X - Y = y - x,$$

or the difference of resistance between the two coils is equal to the resistance of the length of wire between the two positions of equilibrium of the jockey. This resistance can be found with great accuracy by measuring the total resistance of the whole length of the wire, and calibrating it throughout.

**46.** The resistance of a conductor as hitherto considered depends on the shape and dimensions of the conductor as well as on its nature and temperature. It is evidently convenient to form the conception of some quantity which depends only on the nature and temperature of the substance conducting, and not on the particular shape or dimensions of the particular specimen employed. It is usual to take the resistance between opposite faces of a cube of the substance, with a length of side of one centimetre, as the specific resistance of the material. It would, of course, usually be impossible, and always inconvenient, to measure the resistance of such a body directly. Its resistance can, however, be calculated from that of wires, or other convenient masses of the substance, by the aid of the results given on page 117, which show that the resistance of a wire or other conductor of regular form is directly proportional to its length, and inversely proportional to its area of cross section.

The following table of specific resistance is taken chiefly from results given by Fleming and Dewar in 1893. The specific resistances are expressed in microhms per centimetre cube, a microhm being the millionth, or  $10^{-6}$ , of an ohm. A second column gives the resistance in ohms of a column of the material 1 metre in length and 1 square millimetre in cross section.

	Specific resistance in microhms per centimetre cube	Resistance in ohms of column 1 metre by 1 sq. mm.	Mean temperature coefficient per degree between 0° and 100° C.
Silver, annealed	1·468	·01468	·00400

The resistance of alloys is, in general, much higher than that of pure metals, the effect of a very small admixture being some-

\* This figure gives the approximate temperature coefficient of mercury near 20° C., as determined by Matthiessen.

times surprisingly great. The temperature coefficients of alloys are usually lower than those of pure metals, which is an advantage for the construction of resistance-coils, etc., though it is seldom worth while to obtain a low temperature coefficient at the cost of permanence in properties, a quality in which some alloys seem to be deficient. Fleming and Dewar give the following figures.

Alloys	Compositions in per cents.	Specific resistance	Temperature coefficient at 15° C.
Platinum-silver	Pt 33, Ag 66	31·582	·000243
Platinum-iridium	Pt 80, Ir 20	30·896	·000822

Manganin	Cu 84, Mn 12, Ni 4	46·678	·0000

It should be stated here that the resistance of all metallic bodies depends not only on their chemical composition, but also on their physical state. Differences in processes of annealing, etc., which affect the crystalline structure of the metal, are found also to change the specific resistance. Tables of specific resistances and temperature coefficients, then, should only be regarded as strictly applicable to the particular specimens used by the experimenters, though, as approximate guides, such tables may be of general use.

The resistance of metallic conductors, unlike that of electrolytes to be studied hereafter, increases with rising temperature. The most recent and complete experiments on the resistance of metals throughout a wide range are those of Dewar and Fleming, who carried their observations to very low temperatures by the use of liquid air and other liquefied gases. The diminution of resistance at these low temperatures is very marked, and, when curves were drawn, it seemed as though the resistance of all pure metals would vanish in the neighbourhood of the absolute zero. Further experiments, however, at the extreme cold of liquid hydrogen, indicate that, before such temperatures are reached, the curves tend to become parallel to the axis—the resistances to approach a limiting value.

The resistance of wires of pure platinum, and its variation with

temperature, have been the subject of many experiments. It was shown by Callendar that, if such coils of wire be placed in porcelain tubes or protecting cases made of glass, and carefully preserved from all strain by loose winding, the resistance was a function of the temperature only. At a given temperature, the resistance always had a definite value, irrespective of the treatment to which the wire had been subjected previously. This property of consistency is the first and last essential for a trustworthy thermometer, and platinum resistance thermometers are now used extensively not only for high and low temperatures, where other methods are impossible, but also at ordinary temperatures, in cases when the difference of two temperatures is required with extreme accuracy.

Figure 69 shows a platinum thermometer, and Figure 70 shows the form of wire-bridge which is now usually employed to measure its resistance. The electrical arrangements are a modification of those of Carey Foster's bridge, and will be understood by a reference to Figure 68 on page 121.  $E$  and  $E'$  are two equal arms as before. The platinum thermometer is placed in the position marked  $X$ , and in the position marked  $Y$  is inserted a coil of wire made of some substance with a negligible temperature coefficient, or else a coil kept at a constant temperature. In order to allow for the variation with temperature of the conducting leads in the platinum thermometer—a variation impossible to calculate—a pair of dummy leads are fixed alongside the real leads in the tube. These compensating leads are connected together below by a short piece of platinum wire. Whatever irregular heating or cooling happens to the real leads, happens also to the dummy leads, which consequently suffer a change of resistance equal to that of the real leads. The dummy leads are inserted in the arm  $Y$  of the bridge, and thus compensate automatically the variations of resistance of the real leads in the arm  $X$ . As the temperature of the thermometer is raised, the position of equilibrium of the bridge moves along the stretched wire from left to right. The range of the instrument can be increased by adding

Fig. 69.

to the left part of the bridge-wire the resistance coils shown in Figure 70. From the theory of Carey Foster's bridge, it follows

Fig. 70.

that equal increases of resistance of the platinum coil correspond with equal movements in length along the bridge-wire. Thus, by dividing the wire into equal lengths, we obtain a scale of temperature degrees, which we may call the platinum scale. The possibility of thus dividing the wire into equal lengths, corresponding to equal increments of temperature, constitutes the advantage of this form of bridge for the present purpose. If the platinum thermometer were inserted in the arm *S* of the original form of Wheatstone's bridge, shown in Figure 64 on page 119, no such possibility would exist.

Callendar has shown that the platinum temperatures as thus obtained may be reduced to the scale of the gas thermometer by means of the following empirical parabolic formula for the difference between the two scales:

$$t - t_p = \frac{t\delta(t-100)}{10000} = \delta \left\{ \left( \frac{t}{100} \right)^2 - \frac{t}{100} \right\},$$

where  $t$  is the temperature on the gas scale,  $t_p$  the temperature on the platinum scale, both expressed in centigrade degrees, and  $\delta$  is a "difference-constant" the value of which for pure platinum is about 1.5, but varies slightly for different specimens. It can be determined by standardizing an instrument in ice, steam, and the vapour of sulphur, which, at normal atmospheric pressure, boils at a temperature of  $444.5^\circ \text{C.}$  on the scale of the gas thermometer.

The use of the platinum thermometer is extending rapidly both for technical application and also for research-work in physical laboratories. For technical purposes, its advantages comprise the possibility of measuring the temperature from a distance, the extended range of the scale, and the permanent record of varying temperatures which it is now possible to obtain. For scientific research it has been used both at high and low temperatures: for determining the melting points of metals and the boiling points of liquefied gases. The extreme sensitiveness of modern null methods of measuring resistance renders the platinum thermometer by far the most delicate instrument for estimating the differences between two neighbouring temperatures—a difference of the ten-thousandth part of a centigrade degree may be detected with some ease, while careful experiments by Mr E. H. Griffiths have shown that the hundred-thousandth part of a degree may be estimated.

For research purposes, as well as for industrial applications, the possibility of obtaining an automatic and permanent record of changing temperatures is of the utmost importance. This may now be done by the aid of Callendar's Recorder, illustrated in Figure 71. In this instrument, which is a self-adjusting Wheatstone's bridge, a wire-bridge, essentially the same as that shown in Figure 70, is used. The moveable jockey is always in contact with the bridge-wire. The galvanometer is of the moving-coil type, and to the coil is attached a light arm of aluminium, which carries a fork with its prongs lying one on each side of the two metal rims of an ebonite wheel, which, by means of clockwork, is made to revolve slowly. If the bridge is balanced, the fork does not touch the wheel, but, if the resistance of the thermometer changes, the fork makes contact with one rim or other of the wheel. It is necessary to keep the wheel revolving and its rims passing over cleaning brushes, for experience shows that it is impossible otherwise to secure electrical contact between the rims of the wheel and the fork. Contact with the wheel completes an independent electrical circuit—a relay, as it is called—which sets in motion a train of clockwork in one direction or the other, according as the fork touches one rim or the other of the wheel.

A pen, attached to the jockey of the bridge-wire, is moved by

Fig. 71.

this clockwork train over a cylinder of paper, which is itself kept revolving by clockwork. The jockey is thus shifted till the bridge is balanced once more. As long as the temperature is constant, a vertical line is drawn, but, as soon as the thermometer is heated or cooled, the pen moves horizontally. By this means, a continuous curve is obtained, showing the variations of temperature for 24 hours or any other required time. As examples of the use of the recorder the two curves of Figure 72 are given, showing in platinum temperatures, the rates of heating and cooling of two blocks of steel. The points of recalescence are well marked. By the aid of

Fig. 72.

this instrument, experiments have been made by Mr C. T. Heycock and Mr F. H. Neville on the points of solidification of many complicated alloys, and results obtained which could never have been reached without an automatic recorder.

47. As already stated, electromotive forces may be compared electrostatically, roughly by a gold-leaf electroscope, more accurately by a quadrant electrometer. But, in practice, it is usually more convenient to employ some means based on the application of Ohm's law.

The currents produced successively in the same high resistance circuit by two electromotive forces may be estimated by the deflections of a galvanometer or of a voltmeter, which is essentially a moving-coil galvanometer of high resistance. By a second arrangement, the resistance of two circuits may be varied till the same deflection is produced in each case. In these methods, a current is allowed to flow through the cell or other source of electromotive force, and, to obtain the total electromotive force acting round the circuit, the resistance of the cell must be added to that of the rest of the circuit.

A method, which does not involve a knowledge of the resistance of the cell, is based on the use of an instrument known as the potentiometer. A long, thin wire, of high resistance, is stretched by the side of a scale (Figure 73). Through this wire passes

Fig. 73.

maintained by a battery of accumulators or constant primary cells. The potential rises uniformly as we pass along the wire from the end *A* to the end *B*. Thus, if one of the cells to be compared be connected with *A* as shown, and its other terminal be connected through a galvanometer with different points along the wire, some point can be found at which the potential is the same as that of the applied pole of the cell. When this is the case, no current flows through the galvanometer, and the potential-difference between *A* and the point *P* is equal to the electromotive force of the cell. If the second cell be now inserted in place of the first, a new position of equilibrium will be found, the travelling wire being applied at the point *P*<sub>1</sub>. The electromotive force of this second cell must then be equal to the potential-difference

between the points  $A$  and  $P_1$ . But, by applying Ohm's law to the main circuit  $AB$ , we see that the differences of potential between  $AP$  and  $AP_1$  respectively, are proportional to the resistances of the two lengths of wire  $AP$  and  $AP_1$ . If the wire be uniform, these resistances are proportional to the lengths, and thus the ratio between the electromotive forces of the two cells is equal to the ratio of the two lengths  $AP$  and  $AP_1$ .

It is, comparatively speaking, easy to construct a standard resistance-coil having a resistance equal to the practical unit or ohm; but we cannot construct at will a cell having an electromotive force of one volt. We can only take the most constant cell we know, measure once for all its electromotive force in volts, and use the cell thereafter as an arbitrary standard of electromotive force.

One such standard cell is that invented by Latimer-Clark and shown in Figure 74. It consists essentially of mercury in contact with a paste of mercurous sulphate, on which rests a solution of zinc sulphate kept saturated by the presence of crystals of the salt. In this solution dips an amalgamated rod of pure zinc. This cell must not be used to yield a current; but its electromotive force is very constant when no current is taken, and has the value of 1.433 or 1.434 volts at  $15^\circ\text{C}$ . The electromotive force diminishes by 0.00077 volt for each centigrade degree the temperature rises above  $15^\circ$ .

Fig. 74.

The Weston cell consists of the arrangement:

mercury/mercurous sulphate/cadmium sulphate solution/cadmium.

Its electromotive force is 1.018 volt, at  $15^\circ\text{C}$ ., and its temperature coefficient is considerably less than that of the Clark cell.

The principle of the potentiometer is applicable to a number of different purposes. It may, for instance, be used to measure a heavy current in the following manner. The current is passed through a strip of metal of known small resistance  $R$  (Fig. 75).

Between the ends of the strip a difference of potential  $cR$  must then exist, and this potential-difference may be compared with the electromotive force of a standard cell, along the wire of the potentiometer  $AB$ . Thus  $c$  may be determined.

Fig. 75.

A simpler method, more convenient in practice, consists in connecting the terminals of a voltmeter to the ends of the metal strip  $R$ . The resistance of the voltmeter is adjusted to be a known multiple of that of the strip, and, by shunting the current through the voltmeter in this way, its readings may be made to give directly the number of amperes of current flowing through the strip of metal. The voltmeter is thus converted into an ampere-meter or ammeter.

A similar process enables us to compare two resistances which are too small to be examined accurately by the usual means. The same current is passed through the two resistances in series, and the differences of potential between their ends compared by the potentiometer or voltmeter. These potential-differences will be proportional to the two resistances.

48. By the definition of electromotive force, it follows that the work done by a current  $c$ , when it flows for  $t$  seconds through a conductor with a potential-difference  $E$  between its ends, is  $Ect$ . If the current be doing mechanical work by driving a motor, or chemical work by decomposing some compound, part of the total work is thus absorbed. If no such work is being done, the whole of the work of the current must appear as heat in the conductor. If  $H$  be the quantity of heat developed, measured in thermal units, and  $J$  the mechanical equivalent of one thermal unit, then, on the assumptions we have made, we have the relation

$$HJ = Ect.$$

Heating effect  
of an electric  
current.

But, by Ohm's law,  $E$  is equal to  $cR$ , where  $R$  is the resistance of the conductor, at the temperature of the experiment. Thus,

$$HJ = c^2 R t.$$

If we measure the current in electromagnetic units, as, for instance, by the use of a tangent galvanometer, and observe the heat developed in an insulated coil of wire immersed in a calorimeter, the first equation, which, as we have seen, is an immediate consequence of the definition of electromotive force, enables us to determine experimentally the electromotive force between the ends of the coil in absolute electromagnetic units. In the same way, the second equation leads to a knowledge of the resistance of the coils, also in absolute electromagnetic units.

On the other hand, if we know these electrical units from other experiments, the equations enable us to find a value for  $J$ , the mechanical equivalent of the thermal unit. Many experiments have been made for this purpose by Joule, who established the  $c^2 R$  relation by direct observation, by Griffiths, and by other observers. In the latest experiments by Callendar and Barnes, instead of heating a mass of water in an ordinary calorimeter, the current was passed along a platinum wire stretched along the axis of a glass tube through which flowed a stream of water. Observations were made on the temperature of the water before and after passing the tube, and, when a steady state was reached, a value was thus obtained for the rate of heat development. The electromotive force  $E$  between the ends of the wire was measured, and also the electromotive force between the ends of a standard resistance coil of thick wire placed in series with the wire in the calorimeter. The latter observation, with a knowledge of the resistance of the standard coil, which was not appreciably heated by the current, gave the current-strength through the apparatus. Thus the value of  $Ect$  was estimated.

In the equation

$$HJ = c^2 R t$$

the electrical quantities are expressed in absolute electromagnetic units, based on the centimetre, the gramme, and the second. To express our results in practical units, we must remember that the ampere is one-tenth of the absolute unit of current, and the ohm

is  $10^9$  absolute units of resistance. Thus, writing  $C$  for the current in amperes and  $R'$  for the resistance in ohms, and putting for  $J$  its value  $4.18 \times 10^7$  ergs per calorie, we obtain for the number of calories of heat evolved

$$H = 0.239 C^2 R' t.$$

The amount of work done by a current of one ampere flowing for one second through a resistance of one ohm is known as the Joule. It is equivalent to  $10^7$  ergs, or absolute c.g.s. units of work.

The  $c^2 R$  relation, which sometimes goes by the name of Joule's law, shows us that the heat developed by a current does not depend on the direction of that current. Hence, the heating effect has been employed for the measurement of alternating currents, which cannot be estimated by ordinary electromagnetic means. In Cardew's voltmeter, for instance, the heating of a long stretched wire increases its length, and moves a hand over a scale which is graduated empirically.

## CHAPTER VI.

### THERMO-ELECTRICITY.

Thermo-electricity. Application of Thermo-dynamics. Thermo-electric diagrams. Thermo-electric apparatus.

**49.** THE heating effects of currents, due to the resistance of the material of the conductor, have been considered already. There is, however, between thermal and electrical phenomena another connexion, which was discovered in 1821 by Seebeck. He found that, in a closed circuit consisting of two different metals, if the two junctions were kept at different temperatures, a permanent current flowed. Thus, if one junction of a copper-iron circuit be kept in melting ice and the other in boiling water, it will be found that a current passes from copper to iron across the hot junction. If, however, the temperature of the hot junction be raised gradually, the electromotive force in the circuit slowly reaches a maximum, then sinks to zero, and finally is reversed. The currents thus obtained can, of course, perform work, and hereafter we must look for the source of their energy.

In the year 1834, Peltier discovered that, when a current is passed across the junction between two different metals, a reversible evolution or absorption of heat takes place. This effect may be demonstrated by

Fig. 76.

fixing the junction, preferably of bismuth and antimony, in an air-thermometer, as shown in Figure 76. The rate of heat-production is proportional to the first power of the current, and thus the total heat developed may be expressed by  $\Pi ct$ , where  $c$  is the strength of the current,  $t$  the time, and  $\Pi$  the coefficient of the Peltier-effect. Unlike the Joule-effect, which depends on the square of the current, the Peltier-effect is reversible, heat being evolved when the current passes one way across a junction, and absorbed when the current passes in the other direction. With large current-densities, the Peltier-effect is usually small compared with the Joule-effect, but, since the Joule-effect depends on the square of the current, it may be diminished in relative importance by reducing the strength of the current. In ideal conditions, then, when we may imagine that an indefinitely small current passes, the Joule-effect may be neglected compared with the Peltier-effect.

50. It is important to notice the relation between the direction of the thermo-electric current and the sign of the Peltier-effect. Seebeck showed that, in a copper-iron circuit at moderate temperatures, the thermo-current passes from copper to iron across the hotter junction. Peltier found that, if a current be forced by means of an external battery from copper to iron across a junction, the junction is cooled. In general, if a current be forced across a junction in the same direction as the thermo-electric current flows at a hot junction, the junction is cooled, that is, heat is absorbed. Conversely, a current passing in the normal direction across the cold junction of a thermo-electric circuit evolves heat.

In a thermo-electric circuit, then, the passage of the thermo-electric current absorbs heat at the hot junction, and gives up heat at the cold junction. Lord Kelvin recognised that these were the characteristics of a heat-engine, and applied the principles of thermo-dynamics, so largely his own creation, to the elucidation of the problem of the thermo-electric circuit.

In order to apply quantitatively the results of thermodynamical reasoning, it is necessary to be sure that the processes involved are truly reversible. Now, in the present case, two irreversible processes are known to occur: firstly, the frictional

Application of  
Thermo-  
dynamics.

heat developed by the current as investigated by Joule, and secondly the conduction of heat along the metals from hotter to colder places. As indicated above, however, by imagining the currents to be restricted to indefinitely small values, the Joule-effect becomes negligible compared with the reversible heat-effects. The conduction of heat may also be ignored if it proceeds independently of the current, except for the reversible Thomson-effect considered below. This independence it is necessary to assume, though the assumption seems reasonable.

Let us, then, treat the thermo-electric circuit as a reversible heat-engine, which, when unit quantity of electricity passes round the circuit, absorbs a quantity  $\Pi_1$  of heat at an absolute temperature  $T_1$ , gives up a quantity  $\Pi_2$  of that heat to a refrigerator at an absolute temperature  $T_2$ , and converts the rest of it into electrical work, which, when unit quantity of electricity passes round the circuit, is measured by  $E$ , the total electromotive force of the system. By the well-known laws of reversible heat-engines, we now see, firstly, that

$$\frac{\Pi_1}{\Pi_2} = \frac{T_1}{T_2},$$

or 
$$\frac{\Pi_1}{T_1} - \frac{\Pi_2}{T_2} = 0,$$

heat evolved, that is leaving the circuit-system, being taken as negative.

Secondly, by the law of the efficiency of a reversible heat-engine, we have

$$\frac{E}{\Pi_1} = \frac{T_1 - T_2}{T_1},$$

or 
$$E = \frac{\Pi_1}{T_1} (T_1 - T_2) = \frac{\Pi_2}{T_2} (T_1 - T_2).$$

Thus, on the assumption that the Peltier-effects represent the only reversible heat-changes in the system, we see that, if one junction of a thermo-electric circuit be kept at constant temperature, the total electromotive force round the circuit should increase uniformly with the difference of temperature between the junctions. But, as stated above, in certain circuits, the electromotive force is found to rise to a maximum, decrease and then

reverse, as the temperature of one junction is raised continuously. This observation led Lord Kelvin to conclude that the Peltier-effects were not the only reversible heat-changes in a thermo-electric system. He suggested that other reversible heat-effects might be found in the substance of the individual metals, where temperature gradients existed along them, and, by a series of careful experiments, he confirmed this idea experimentally. In a copper bar, heat is carried with the electric current when it flows from hot regions to cold ones, and, on the other hand, when the current flows from cold regions to hot ones, these hot parts of the bar are cooled. In iron these effects are reversed. On the analogy of the flow of a fluid along a channel, we may describe these results by saying that the specific heat of electricity is positive in copper, but negative in iron. If  $\sigma$  denote this specific heat of electricity, and  $\delta T$  the small difference between the temperatures of two points on a bar, then the heat absorbed, when unit quantity of electricity passes from one point to the other, may be expressed as  $\sigma \delta T$ , and this relation serves to define the quantity  $\sigma$ .

The essential difference between the evolution of heat due to this Thomson-effect, and that due to the Joule-effect, should be noted. The frictional heat varies as  $c^2 R$ , and vanishes in the ideal condition of a very small current. The Thomson-effect varies as the first power of the current, and thus is reversed and becomes a heat-absorption when the current is reversed. The Thomson-effect, then, like the Peltier-effect, is an integral part of the reversible heat-engine which is constituted by a thermo-electric circuit. As the current passes from a region of temperature  $T$  to one of temperature  $T - \delta T$ , heat to the amount of  $\sigma \delta T$  is absorbed. Figuratively we may represent the wire as composed of a number of little elements of volume, at the junctions between which occur reversible heat-effects, similar to the Peltier-effects at the junctions between the wires of different metals. Thus, in passing along a wire from one end where the absolute temperature is  $T_1$  to the other end where it is  $T_2$ , an amount of heat is absorbed equal to the sum of all the small quantities  $\sigma \delta T$  or, in the notation of the integral calculus,  $\int_{T_1}^{T_2} \sigma dT$ . Along the other wire of the circuit, where, as we pass with the current, the change of temperature is

reversed, the absorption of heat is, in like manner,  $\int_{T_2}^{T_1} \sigma' dT$  or  $-\int_{T_1}^{T_2} \sigma' dT$ .

Instead of a simple heat-engine, with one source and one refrigerator, we have in the thermo-electric circuit a complex engine, with a number of sources from which heat is absorbed, and a number of refrigerators to which heat is given up. Some of these sources and refrigerators are the main junctions, where Peltier-effects occur; others are the hypothetical junctions between the little elements of volume in the individual wires, where, owing to a temperature gradient, Thomson-effects are found. But all these heat-effects are reversible; they all are involved in the working of the thermo-electric engine.

When one unit of electricity passes round the circuit, the work done at each junction, or between each pair of volume elements, is the electrical equivalent of the heat there absorbed, somewhat as the work done by expansion in contact with the hot body in Carnot's theoretical heat-engine, when using an ideal gas as the working substance, is the mechanical equivalent of the heat then absorbed into the cylinder. And, as in Carnot's engine, some of this work is reconverted into heat when the working substance is compressed in contact with the cold body, so, in our thermo-electric engine, part of the electrical energy is reconverted into heat at the other Peltier-junction and at the interfaces, if any, between volume-elements in the wires, where the sign of the Thomson-effect requires an evolution of heat.

Again, in Carnot's engine, according to the principle of the conservation of energy, the balance of useful work is the equivalent of the excess of the heat energy obtained from the source over that given up to the condenser. So here, the balance of electrical energy, obtained per unit electric transfer, is the equivalent of the excess of the heat absorbed at some places in the circuit over that given up at other places. But, this quantity of electrical energy is the effective electromotive force  $E$  acting round the circuit, and thus we get

$$E = \Pi_1 - \Pi_2 + \int_{T_1}^{T_2} (\sigma - \sigma') dT.$$

Again, as we have shown that, for the simple Peltier-circuit (page 136),

$$\frac{\Pi_1}{T_1} - \frac{\Pi_2}{T_2} = 0,$$

so, for our present more complex case, we may show that

$$\frac{\Pi_1}{T_1} - \frac{\Pi_2}{T_2} + \int_{T_1}^{T_2} \left( \frac{\sigma}{T} - \frac{\sigma'}{T} \right) dT = 0,$$

an equation which expresses the well-known relation of the conservation of entropy in a reversible system.

Now, by differentiating this expression, that is by finding the value of its rate of change with temperature, we get rid of the integration sign, and may write

$$\frac{d}{dT} \left( \frac{\Pi}{T} \right) + \frac{\sigma - \sigma'}{T} = 0.$$

Thus,

$$\begin{aligned} \sigma - \sigma' &= T \frac{d}{dT} \left( \frac{\Pi}{T} \right) \\ &= T \left\{ \frac{1}{T} \frac{d\Pi}{dT} - \frac{\Pi}{T^2} \right\} = \frac{d\Pi}{dT} - \frac{\Pi}{T}. \end{aligned}$$

Our equation for  $E$  now gives

$$\begin{aligned} E &= \Pi_1 - \Pi_2 + \int_{T_1}^{T_2} \left\{ \frac{d\Pi}{dT} - \frac{\Pi}{T} \right\} dT \\ &= \int_{T_2}^{T_1} \frac{\Pi}{T} dT. \end{aligned}$$

Differentiating this expression, we obtain

$$\frac{dE}{dT} = \frac{\Pi}{T},$$

or

$$\Pi = T \frac{dE}{dT}.$$

Thus the coefficient of the Peltier-effect appears in this expression as measured by the product of the absolute temperature and the rate of change with temperature of the total electromotive force  $E$  round the circuit. Our original equation for  $E$ , however, on page 138, showed each Peltier-effect contributing

towards the total electromotive force, as a local potential-difference at the junction. These two aspects of the Peltier-effect should be remembered. On the theory here given, the Peltier-effect at a junction is the thermal equivalent per unit electric transfer of the local step of potential at the interface. But it is also measured by the product of the absolute temperature of the junction and the rate of change with temperature of the total electromotive force of the circuit (not the local electromotive force at the junction).

51. The properties of a thermo-electric circuit may be illustrated by means of a diagram in a manner due originally to the late Prof. Tait. The diagrams are based on two experimental principles:

Thermo-  
electric  
diagrams.

(1) The electromotive force round a circuit when the junctions are kept at temperatures  $T_1$  and  $T_3$  is the sum of the electromotive forces when the junctions are kept first at  $T_1$  and  $T_2$ , and then at  $T_2$  and  $T_3$ .

(2) The electromotive force round a circuit of the two metals  $A$  and  $C$  is the sum of the electromotive forces round two circuits, one composed of the metals  $A$  and  $B$ , and another composed of the metals  $B$  and  $C$ , the temperature limits being the same for all the circuits.

It was found by Le Roux that in lead the Thomson-effect is inappreciable. Hence it is convenient to take lead as the standard metal, and draw the thermo-electric diagram of another metal with reference to lead. By the second of the experimental results enunciated above, it follows that the relative position of two curves drawn to represent the thermo-electric properties of two metals with reference to lead, represents the thermo-electric properties of those two metals with reference to each other.

The most obvious method of plotting the results of thermo-electric measurement is to take the temperature of one junction as abscissa and the electromotive force round the circuit as ordinate, the temperature of the other junction being kept constant. Curves approximating to parabolas may thus be obtained. A more convenient and usual method, however, consists in taking as abscissae

the absolute temperatures, and as ordinates a quantity called the thermo-electric power, which is defined as the electromotive force round the circuit when the junctions are kept half a degree above and below the temperature in question. It is clear that this definition comes to making the thermo-electric power equal to the quantity  $dE/dT$ . In general, when the diagrams are drawn with reference to the standard substance lead, these curves are found to be straight lines.

In Figure 77, let  $OL_1$  be taken as the axis to represent the

Fig. 77.

standard metal lead. Let  $FG$  and  $EH$  be the curves for the thermo-electric power of two metals  $A$  and  $B$  with reference to lead. Then it follows that the thermo-electric power of  $A$  with reference to  $B$  is represented by the difference-ordinate  $FE$  at a temperature of  $L_2$  and by  $GH$  at a temperature of  $L_1$ .

Since the length of the ordinate  $L_2F$  denotes the electromotive force round a circuit composed of lead and the metal  $B$  per degree difference of temperature, it follows that, for a small temperature difference  $\delta T$ , the electromotive force is represented by the area of a narrow strip of height  $L_2F$ , and of breadth  $\delta T$ . Thus, for the considerable temperature-difference  $L_2L_1$ , the total electromotive force round the circuit is represented by the sum of the areas of the corresponding strips, that is, by the area  $L_2FGL_1$ . Similarly,

for the two metals  $A$  and  $B$ , the electromotive force round the circuit is represented by the area  $FEHG$ .

Now let us consider the Peltier-effect at the hot junction at the temperature  $OL_1$ . We have shown on page 139 that the Peltier-effect is equal to  $TdE/dT$ , and the difference-ordinate  $GH$  is the thermo-electric power or  $dE/dT$ . Thus the electrical equivalent of the Peltier-effect is represented by the area  $HGUVH$ . Similarly, the Peltier-effect at the cold junction at the temperature  $OL_2$  is represented by the area  $EFTSE$ .

Our expression for the total electromotive force, obtained from the principle of the conservation of energy, namely

$$E = \Pi_1 - \Pi_2 + \int_{T_2}^{T_1} (\sigma - \sigma') dT,$$

shows that the electromotive force round the circuit is the algebraic sum of the thermal equivalents of the Peltier- and Thomson-effects. The total electromotive force is represented by the area  $HGFEH$ , the positive Peltier-effect at the hot junction by the area  $HGUVH$ , and the negative Peltier-effect at the cold junction by the area  $EFTSE$ . Now the electromotive force area  $HGFEH$  may be made up thus:

$$\text{Area } HGFEH = \text{area } HGUVH + \text{area } GFTUG - \text{area } EFTSE \\ - \text{area } HESVH.$$

Identifying the areas  $HGUVH$  and  $EFTSE$  with the Peltier-effects in the equation for  $E$ , we see that the Thomson-effect in the metal  $A$  must be represented by the area  $HESVH$ , and the Thomson-effect in the metal  $B$  by the area  $GFTUG$ . Thus all the properties of the thermo-electric circuit are represented on the diagram.

Figure 78 shows a thermo-electric diagram for a number of metals. The abscissae represent temperatures measured on the centigrade scale, and the ordinates the thermo-electric powers in microvolts per degree. From what has been said, it will be clear that the thermo-electric behaviour of any pair of metals may be tabulated completely on such a diagram, in a form convenient for future use. It is seen that the Peltier-effect for iron and copper vanishes at a temperature of about  $280^\circ\text{C}$ . When the hot

junction reaches that temperature, called the neutral point, the total electromotive force of a copper-iron circuit, with its cold junction kept at a constant temperature, is a maximum; beyond that temperature the area between the two lines is to be reckoned negative, and subtracted from the area to the left of the neutral point.

Fig. 78.

- 52.** Thermo-electric currents, which are often an inconvenience in delicate measurements of resistance, have been applied with advantage in two ways. A thermo-couple is used sometimes as a practical thermometer, and a thermo-couple, or series of thermo-couples, is employed to detect and measure incident radiation of small intensity.

Thermo-  
electric  
apparatus.

As a thermometric instrument, the thermo-couple is chiefly of use where high temperatures are to be estimated approximately, as in many manufacturing operations. The couple is generally made of wires of platinum and of an alloy of either platinum and iridium, or platinum and rhodium. All these metals are very infusible, and very high temperatures may be measured. To the usual order of accuracy required, it is enough to keep one junction at the temperature of the atmosphere, and place the other in the furnace or other enclosure to be examined. The temperature may be read off directly by proper graduation of a millivoltmeter. An

apparatus of this kind is illustrated in Figure 79. The thermocouple is enclosed in an infusible porcelain tube.

Fig. 79.

An instrument which was long used to detect the incidence of radiation is shown in Figure 80. It is known as the thermopile,

Fig. 80.

and consists of a number of bars of bismuth and antimony soldered together in series, and placed so that all similar junctions, where a current passing round the circuit would flow from bismuth to antimony, are collected together at one face of the pile. If this face becomes slightly hotter than the other, an electromotive force is set up at each junction in the face. These electromotive forces are in the same direction, and will drive a current through a galvanometer placed in the circuit. By using a very low resistance galvanometer, and keeping all the circuit of low resistance, the apparatus will be found to be moderately sensitive.

Much greater, however, is the sensitiveness of the radio-micrometer invented by Mr Vernon Boys. A single loop of pure copper wire has its ends soldered to a bismuth-antimony junction, to which is attached a small blackened copper disc. When radiation falls on the disc it is heated, and the junction with it. A current is thus set up round the copper loop. The loop is suspended between the poles of a strong permanent magnet, forming a galvanometer of the moving-coil type. A light mirror attached to the thermo-junction is used to reflect a spot of light on to a scale or the image of a scale into a telescope. It is said that this instrument will detect the radiation from a candle-flame at a distance of more than a mile.

## CHAPTER VII.

### ELECTROMAGNETIC INDUCTION.

Faraday's experiments. Quantitative Laws of Induction. Coefficients of induction. Analogy between self-induction and inertia. Electrical oscillations. Electromagnetic machinery. Dynamos and motors. Transformers and Induction Coils.

**53.** THE induction of statical charges of electricity by other charges, and the similar action exerted by magnets on soft iron, suggested to the early experimenters that like effects should be obtained with the steady currents given by voltaic cells. Faraday, for instance, wound two helices of insulated wire on the same wooden cylinder, but could observe no deflection of a galvanometer inserted in one coil when a steady current was maintained through the other by a powerful voltaic battery.

His first successful experiment, which opened a new era in the history of electrical science, was thus described to the Royal Society by Faraday on November 24, 1831.

"Two hundred and three feet of copper wire in one length was wound round a large block of wood; other two hundred and three feet of similar wire were interposed as a spiral between the turns of the first coil, and metallic contact everywhere prevented by twine. One of these helices was connected with a galvanometer, and the other with a battery of one hundred pairs of plates four inches square, with double coppers, and well charged. When the contact was made, there was a sudden and very slight effect at the galvanometer, and there was also a similar slight effect when the contact with the battery was broken. But whilst the voltaic current was continuing to pass through the one helix, no galvano-

metrical appearances nor any effect like induction upon the other helix could be perceived, although the active power of the battery was proved to be great, by its heating the whole of its helix, and by the brilliancy of the discharge when made through charcoal.

"Repetition of the experiment with a battery of one hundred and twenty pairs of plates produced no other effect; but it was ascertained, both at this and the former time, that the slight deflection of the needle occurring at the moment of completing the connexion, was always in one direction, and that the equally slight deflection produced when the contact was broken, was in the other direction.

"The results which I had by this time obtained with magnets led me to believe that the battery current through one wire, did, in reality, induce a similar current through the other wire, but that it continued for an instant only, and partook more of the nature of an electrical wave passed through from the shock of a common Leyden jar than of the current from a voltaic battery, and therefore might magnetize a steel needle, though it scarcely affected the galvanometer.

"This expectation was confirmed; for on substituting a small hollow helix, formed round a glass tube, for the galvanometer, introducing a steel needle, making contact as before between the battery and the inducing wire, and then removing the needle before the battery contact was broken, it was found magnetized.

"When the battery contact was first made, then an unmagnetized needle introduced into a small indicating helix, and lastly the battery contact broken, the needle was found magnetized to an equal degree apparently as before; but the poles were of a contrary kind."

With the much more delicate galvanometers we now possess, it is easy to repeat Faraday's experiments with the primary current derived from a single voltaic cell, and to show that similar transient currents are produced by moving the primary and secondary circuits relatively to each other, or by moving a permanent magnet relatively to a coil connected with a galvanometer.

In all such cases it will be seen that the number of tubes of magnetic induction passing through the secondary circuit is altered,

and, in general, we may say that a current is induced in the same direction as the primary current (or in the same direction as the current equivalent to the inducing magnet) whenever the number of tubes of magnetic induction threading the secondary circuit is diminished, and in the contrary direction when the number of magnetic tubes is increased.

Since currents flowing in the same direction attract each other, it follows that, when a circuit carrying a current is moved nearer to a second circuit, the inverse current induced therein causes the two circuits to repel each other. When the primary recedes, the two similar currents attract each other. Thus, in each case, the induced current is in that direction which tends to stop the motion producing it. This result, which is known as Lenz's law, is an example of the universal physical principle whereby any external change acting on a system produces within the system a change which tends to resist the effects of the external change. This principle is sometimes called the law of least action. In the form of Lenz's law, the principle is often of use in enabling us to see at a glance the direction of an induction current.

Faraday's experiments led him at once to an explanation of the action of the apparatus known as Arago's disc. If a copper disc be rotated in its own horizontal plane beneath a compass-needle, which is shielded from the air draughts of the disc by an interposed glass screen, the needle will be found to be dragged round with the disc. Explanations of this phenomenon had been offered, referring it to "induced magnetism" in the copper disc. Faraday saw that, by motion in the magnetic field of the needle, secondary eddy currents were set flowing in closed curves in the substance of the disc. These currents will be in directions such that they tend to stop the relative motion of the needle and disc. The needle, therefore, follows the disc as it rotates.

The current induced in one coil by starting or stopping a current in another is much greater if the coils be wound on an iron core, the effect being proportional to the magnetic permeability. This shows that it is the change in the magnetic induction, and not that in the magnetic force, which is involved.

By winding a primary coil over an iron ring, and using as a secondary a few turns of wire surrounding both primary and iron,

it is possible to investigate the magnetic properties of the iron, and to obtain hysteresis curves similar to those given in § 33, Chapter IV. In many cases this is the most convenient method to adopt.

**54.** Faraday showed that the induced currents were greater in proportion as the rate of change of the magnetic field was increased, but the exact quantitative magnitude of the induced electromotive force was first given by F. E. Neumann in 1845.

Quantitative  
laws of  
induction.

We may deduce by dynamical principles the laws of induction of currents from the known mechanical forces on currents placed in magnetic fields. Ampère's formula for the mechanical force  $F$  on an element of current  $c$  of length  $\delta l$ , when placed in a magnetic field at an angle  $\theta$  with the direction of the magnetic induction  $B$ , is (p. 105)

$$F = c\delta l B \sin \theta,$$

the force acting at right angles both to the current and to the magnetic induction.

Let us imagine that the element  $ab$  of the circuit in Figure 81 moves with constant velocity through a distance  $\delta x$  at right angles to itself in the direction of the force. To maintain the continuity of the circuit we may suppose that  $ab$  slides along parallel rails, or that its ends float along mercury troughs.

The work done by the circuit is measured by the force into the distance or

$$cB \sin \theta \delta l \delta x.$$

Now  $\delta l \delta x$  is the area between the rails moved over by the current-element; that is, it is the increase of area of the circuit. The magnetic induction  $B$  denotes the number of tubes of induction per unit area normal to their direction. Thus  $B \sin \theta \delta l \delta x$  is equal to  $\delta N$ , the increase in the number of tubes of induction through the circuit produced by the movement of the current-element  $ab$ , and the work done during the movement may be written as  $c\delta N$ .

Fig. 81.

Now let us suppose that the current in the circuit is maintained by a battery with an electromotive force  $E$ . During the time  $\delta t$  of the movement of the element  $ab$ , the battery will do a quantity of work equal to  $Ec\delta t$ . By the principle of the conservation of energy, part of this energy is used in doing work  $c\delta N$  against the magnetic forces, and the rest is expended in the circuit as a quantity of heat  $c^2R\delta t$ . Thus

$$Ec\delta t = c^2R\delta t + c\delta N,$$

or

$$c = \frac{E - dN/dt}{R}.$$

Hence there is an additional electromotive force in the circuit equal to the rate of decrease of the number of tubes of induction which thread the circuit. We may imagine that the original current and electromotive force are made as small as we please—the result still holds. It follows that, even in a circuit with no original current, one must be induced by a change in the flux of induction through the circuit, though in this case the work must be done by some external agency, instead of by a battery in the circuit. Thus, in general, we obtain the following result:—When the magnetic induction through any circuit is changed, an induced electromotive force is set up, equal to the rate of decrease of the number of lines of induction which thread the circuit.

This result, which we have deduced from the known magnetic forces of currents, may be verified or established by direct ex-

Fig. 82.

periment. Two coils of wire are placed near each other, as shown in Figure 82. In circuit with one coil is connected a battery, a resistance box, a tangent galvanometer, and a reversing key. In circuit with the other coil is placed a second resistance box and a ballistic galvanometer (see page 109). When a steady current passes through the first or primary coil, there is no current in the secondary, but, if the primary current be started suddenly, stopped or reversed, a throw of the ballistic galvanometer indicates a rush of current through the secondary circuit.

The primary current produces a magnetic field, and some of the tubes of magnetic induction from it pass through the secondary coil. If the number of these tubes be altered as described above, a transient current will be observed. Suppose, for instance, that we reverse the primary current. Then all the tubes of induction, which at first threaded the secondary coil in one direction, will be reversed suddenly, so that, if  $N$  be the number of tubes originally passing through the secondary coil, the number finally passing is  $-N$ , and the sudden change in the number is  $2N$ . The magnetic field, and therefore  $N$ , is proportional to the strength of the primary current; thus any required change in  $N$  can be obtained by altering the strength of the current which is to be reversed; the current used can be measured by the tangent galvanometer. By such experiments we can show that the total quantity of electricity passing in the secondary current is proportional to the total change in the number of tubes of magnetic induction threading the secondary circuit, and inversely proportional to the total resistance of the secondary circuit. Therefore, if, owing to a change  $\delta N$  in the number of tubes of induction through the circuit, a current  $c$  pass in a circuit of resistance  $R$  for a small time  $\delta t$ , we may write

$$c\delta t \propto \frac{\delta N}{R}.$$

By Ohm's law, the product of  $c$  and  $R$  is the electromotive force  $E$  in the circuit, thus

$$E \propto \frac{\delta N}{\delta t},$$

or the electromotive force must be proportional to the rate of change in the number of tubes of induction.

In order to obtain a quantitative relation, we must use two coils placed in such a position that it is possible to calculate the number of tubes of induction which threads one coil when unit current passes in the other. With two large coils placed parallel to each other as shown in Figure 82, it would be difficult to calculate the number of tubes. To avoid this difficulty, a form of apparatus may be used in which the magnetic field of the primary current is uniform. For instance, the field due to a current  $c$  in a large circular coil with  $n_1$  turns of wire of radius  $r_1$  is nearly uniform near the centre, and equal to  $2\pi n_1 c / r_1$  (page 107). In air, this expression represents the number of tubes of induction per unit area normal to their direction; and the number of tubes through a small coil of  $n_2$  turns with radius  $r_2$  placed at the centre of the large coil with the planes of the two coils coincident, is  $\frac{2\pi n_1}{r_1} \pi n_2 r_2^2$ , or  $\frac{2\pi^2 n_1 n_2 r_2^2}{r_1}$ , when unit current flows round the large coil.

Again, the field within a long solenoid is  $4\pi n c$ , where  $n$  is the number of turns of wire per unit length. When placed coaxially within the solenoid, a small circular coil of  $n_2$  turns with radius  $r_2$  will be threaded by a number of tubes of induction equal to  $4\pi n \cdot \pi n_2 r_2^2$  or  $4\pi^2 n n_2 r_2^2$  when unit current passes through the solenoid. By either of such pieces of apparatus the laws of induction may be verified quantitatively by the use of formulæ obtained in this book. The result of the experiments shows that the total electric transfer round the circuit is, when expressed in absolute electromagnetic units, with proper attention to signs, equal to the total decrease in the number of tubes of induction divided by the resistance of the circuit. Thus, as before,

$$c\delta t = -\frac{\delta N}{R},$$

and

$$E = -\frac{dN}{dt}.$$

It should be noted that this induced electromotive force acts in the primary coil as well as in the secondary, for all its own lines of induction must pass through the primary circuit. On making a current in a coil, a transient electromotive force acts in the negative direction, and the current is prevented from reaching

instantaneously its full value. So also on breaking the circuit, the positive induced electromotive force tends to prolong the current. In either case, the result is that no abrupt change can occur in the total number of tubes of induction which thread the circuit.

It should be noticed that, with two circuits, the induced secondary current will itself induce a tertiary electromotive force in the primary coil. When a primary current in what we will call the positive direction is started, a secondary current is produced in the negative direction. The starting of this will re-induce an electromotive force in the positive direction in the primary. It will thus help the primary current to start, and to increase towards its maximum value. The presence of a second circuit then, will diminish the effect of self-induction in any circuit; it will enable an applied electromotive force sooner to establish its current, and make it easier for that current to cease when the electromotive force is removed. This effect is of great practical importance.

**55.** The number of tubes of magnetic induction, which thread a circuit, when unit current is flowing round it, is called the coefficient of self-induction of the circuit, and the number of tubes which thread one circuit when unit current is flowing round another is called the coefficient of mutual induction between the two circuits. The importance of these coefficients will be clear if we notice that the total number of tubes threading a circuit, when a current  $c$  passes, is  $Lc$ , where  $L$  is its coefficient of self-induction. Thus the induced electromotive force in the circuit,  $-dN/dt$ , is equal to  $-Ldc/dt$ . Similarly the induced electromotive force in one circuit, due to a change in the current through another, is  $-Mdc/dt$ , where  $M$  is the coefficient of mutual induction. Hence, if we know the coefficient of induction and the rate of change of the primary current, we can find at once the secondary electromotive force.

We have seen already that it is possible to calculate the coefficient of mutual induction in simple cases. An arrangement of practical importance consists of two co-axial solenoids of equal length  $l$ . Let  $r_1$  and  $n_1$  denote respectively the radius and the number of turns of wire per unit length of the inner coil, and  $r_2$  and  $n_2$  the corresponding quantities for the outer coil. If unit

current flow round the inner coil, the field of magnetic induction within it is  $4\pi n_1$ , which measures the number of tubes per unit area. The total area of the inner coil is  $\pi r_1^2$ , and the total magnetic flux through the inner coil is  $4\pi^2 n_1 r_1^2$ . All these tubes of induction must pass through each turn of wire of the outer solenoid, which surrounds the inner solenoid. The number of such turns is  $n_2 l$ , and therefore the coefficient of mutual induction is  $4\pi^2 l n_1 n_2 r_1^2$ . Now let us suppose that the current is sent through the outer coil. When the current is unity, the magnetic field within is  $4\pi n_2$ , and the number of tubes of induction which pass through the total area (counting that of each turn of wire) of the inner coil, which only fills part of the area of cross-section of the outer coil, is  $4\pi n_2 n_1 l \pi r_1^2$  or  $4\pi^2 l n_1 n_2 r_1^2$ . It follows that the number of tubes of induction passing through the outer coil when unit current flows through the inner is equal to the number which passes through the inner when unit current flows round the outer. This justification of the term "mutual induction" will be shown later to apply to every case.

From what has been said, it follows that the coefficient of self-induction of a single solenoid is  $4\pi n \cdot n l \pi r^2$  or  $4\pi^2 l n^2 r^2$ .

For a small circular coil with  $n_2$  turns of radius  $r_2$  placed at the centre of a large circular coil with  $n_1$  turns of radius  $r_1$ , the planes of the coils being parallel, the coefficient of mutual induction must, by the last section, be  $2\pi^2 n_1 n_2 r_2^2 / r_1$ .

Other simple cases may be solved by the aid of more complicated mathematical analysis, but it is often only possible to determine coefficients of induction by direct experiment. The apparatus shown in Figure 82 on page 150 may be used, and the number of tubes of magnetic induction threading the secondary coil when unit current passes round the primary may be calculated from a measurement of the total electric transfer round the secondary when a known current in the primary is reversed. Here we assume the laws of induction which, on page 151, we used the apparatus to verify.

We have shown above, for one particular case, that the coefficient of mutual induction between two coils is the same whichever coil is used as primary. It is possible to establish

this result in a general form by a method which brings out other points of interest.

Let us calculate the mutual potential energy of two currents, by supposing them to be replaced by their equivalent magnetic shells.

The potential at a point due to a magnetic shell of strength  $S_1$  is, as we saw on page 98, equal to  $S_1\Omega$ , where  $\Omega$  is the solid angle which the shell subtends at the point. The work done in bringing up from infinity a pole of strength  $m$  to the point is  $S_1\Omega m$ .

The second shell, of strength  $S_2$  and thickness  $\delta x$ , may be resolved into a number of minute magnets, each of length  $\delta x$  and area of cross-section  $\delta\alpha$ . Now, the strength of a shell is the magnetic moment per unit area, or  $\frac{m\delta x}{\delta\alpha}$ . Therefore  $m$  is  $S_2 \frac{\delta\alpha}{\delta x}$ .

The potential energy of the first shell and one pole of the elementary magnet in the second shell is

$$S_1 S_2 \frac{\delta\alpha}{\delta x} \Omega.$$

Now, as we pass from one end of the elementary magnet of the second shell to the other, the solid angle subtended by the first shell changes. Its rate of change as we pass along the axis of the elementary magnet is  $\frac{d\Omega}{dx}$ , and the total change is  $\frac{d\Omega}{dx} \delta x$ .

Thus the new value of the solid angle is  $\Omega - \frac{d\Omega}{dx} \delta x$ . The pole at the other end of the elementary magnet has a strength  $-m$  or  $-S_2 \frac{\delta\alpha}{\delta x}$ , and its mutual potential energy with the first shell is the work done in bringing it to its proper position from an infinite distance, or

$$-S_1 S_2 \frac{\delta\alpha}{\delta x} \left( \Omega_1 - \frac{d\Omega}{dx} \delta x \right).$$

For both poles of the element of the second shell the work done is

$$S_1 S_2 \frac{\delta\alpha}{\delta x} \cdot \frac{d\Omega}{dx} \delta x = S_1 S_2 \frac{d\Omega}{dx} \delta\alpha.$$

To extend the result to the whole of the second shell, we must integrate this expression over the whole area, and write

$$S_1 S_2 \int \frac{d\Omega}{dx} d\alpha.$$

But, by principles similar to those used on page 26, it follows that the magnetic induction in any direction is measured by the rate of fall of magnetic potential in that direction. Hence, the normal induction at any point on the second shell due to the first shell is  $-S_1 \frac{d\Omega}{dx}$ . This measures the number of tubes of magnetic induction passing through unit area, and through an area  $\delta\alpha$  the number will be  $-S_1 \frac{d\Omega}{dx} \delta\alpha$ . Therefore, the total magnetic flux, or the total number  $N_1$  of tubes of magnetic induction, through the whole area of the second shell due to the first shell will be

$$N_1 = -S_1 \int \frac{d\Omega}{dx} d\alpha.$$

Hence, the work done in bringing the second shell to its position against the magnetic forces of the first, that is, the mutual potential energy of the two shells, is  $-S_2 N_1$ , the product of the strength of the second shell and the magnetic flux passing through it from the first shell.

By calculating in a similar manner the work done in bringing up the first shell while the second is fixed, we obtain, as a new expression for the same mutual potential energy,  $-S_1 N_2$ , and hence

$$S_1 N_2 = S_2 N_1.$$

Finally, let us replace the shells by two currents of equivalent strengths  $c_1$  and  $c_2$ . We have

$$c_1 N_2 = c_2 N_1.$$

If unit current be flowing in one circuit, the magnetic flux through the other is defined as the coefficient of mutual induction; and since, when both currents are of unit strength,  $N_2$  is equal to  $N_1$ , the fluxes are equal, that is, the number of tubes of magnetic induction passing through the second circuit when unit current flows round the first, is equal to the number of tubes passing through the first when unit current flows round the second.

We see also that the coefficient of mutual induction between

two circuits measures their mutual potential energy when unit current circulates round each.

**56.** Since the induced electromotive forces in a coil through which passes a varying current are in the opposite direction to the current when it is increasing, and in the same direction as the current when it is diminishing, the effect of self-induction is to tend to check the change in current strength. Now the inertia of a dynamical system tends to retard its being set in motion when at rest, and to keep it in motion when once started. Thus, just as inertia tends to prevent a change in velocity, so self-induction tends to prevent a change in current-strength.

If the self-induction of a coil be very high, as it is in coils of many turns of wire, especially if wound on iron cores, the effect of self-induction will be so great that a rapidly alternating electromotive force will produce hardly an appreciable current. A rapidly alternating current, then, will pass along a straight short path, even if of high resistance, rather than through a low resistance circuit of high inductance, through which a steady current passes readily. A coil which, in this way, is nearly impassable to rapidly alternating currents while allowing direct currents to flow through it readily is often of practical use, and is called a choking coil.

The quantitative investigation of this effect needs the solution of a differential equation; but, even if the proof cannot be followed, the result is of great interest. Let an external electromotive force, which varies harmonically with the time  $t$  and is represented by  $E \cos pt$ , be applied to a circuit with a coefficient of self-induction  $L$  and a resistance  $R$ . This electromotive force makes  $p/2\pi$  complete alternations per second, changing direction  $p/\pi$  times per second. If  $c$  be the current through the coil, the primary electromotive force is  $Rc$ , while the secondary is  $Ldc/dt$ . Thus

$$L \frac{dc}{dt} + Rc = E \cos pt.$$

The solution of this equation is

$$c = \frac{E \cos(pt - \alpha)}{\{R^2 + L^2 p^2\}^{\frac{1}{2}}},$$

where  $\tan \alpha = Lp/R$ .

Analogy  
between self-  
induction and  
inertia.

The maximum value of the electromotive force is  $E$ , while that of the current is  $E/\{R^2 + L^2 p^2\}^{\frac{1}{2}}$ . Now, if a steady electromotive force  $E$  were acting, the steady current would be  $E/R$ . Thus the inertia of the circuit, due to its self-induction, makes the effective resistance greater for alternating currents than for steady currents, and equal to  $\{R^2 + L^2 p^2\}^{\frac{1}{2}}$ . This effective resistance is called the impedance of the circuit.

The equation for the current shows that the phase of the current lags behind that of the electromotive force. When the alternations are so rapid that  $Lp$  is large compared with  $R$ ,  $\tan \alpha$  is very large, and hence  $\alpha$  approaches a right angle or  $\pi/2$ . The current in the coil will now be greatest when the electromotive force is zero, and will vanish when the electromotive force is a maximum. Allowance must often be made for this lag of the current in electromagnetic machinery.

The subject of alternating currents has now become of great industrial importance, and many theoretical investigations have been made thereon. From the experimental side, much light has been thrown on the phenomena by the use of an instrument known as the oscillograph, which, first described by M. Blondel, is, in its present form, the invention of Mr Duddell. In its essence, this instrument is a galvanometer of the moving-coil type, the moment of inertia of the coil being so much reduced, and the restoring couple so much increased, that the natural period of vibration is reduced to the  $1/5000$  or the  $1/10000$  of a second. By the friction of a viscous oil the motion of the coil is made "dead-beat," that is, the system moves at once to its position of equilibrium, and no series of swings follows a displacement. In consequence of these arrangements, the apparatus will follow the alternations of a current with a frequency of 100 or more per second. The apparatus is represented diagrammatically in Fig. 83. The coil is replaced by a loop of two delicate phosphor-bronze strips, *ss*, arranged parallel to each other and stretched by a light spring so as to lie vertically between the poles of a powerful permanent or electro-magnet. The strips run through minute gaps in the magnetic circuit, and these gaps are filled with viscous oil. When a current passes round the loop, one strip moves forward and the other back, just as the coil of a d'Arsonval galvanometer turns through an angle. The relative

movement of the two strips is made visible by fixing to them a very small and light mirror  $M$ , so that any relative shift rotates

Fig. 83.

the mirror about a vertical axis. The horizontal displacement of a spot of light may thus be made to measure the instantaneous value of the current. With an alternating current the image of this spot of light would oscillate backwards and forwards. If this image be received on a photographic screen which is made to move vertically, the image traces out the time-current curve, which can then be developed as a permanent photographic record. By using a high resistance in the circuit, the oscillograph may be used as a voltmeter, while, by shunting the current, it can be made into an ammeter. By combining two instruments in this way into a double oscillograph, simultaneous curves may be obtained of

the current  $C$ , and the applied electromotive force or potential difference  $V$ . In Figure 83 *a* are shown two such curves, given by an alternating current machine. The lag of the current, referred to above, is well seen.

We have supposed that a periodic electromotive force may be represented by a simple harmonic function of the time—that it varies as the cosine of an angle proportional to the time. Such a curve would somewhat resemble the curve marked  $V$  in Figure 83 *a*. Often, however, the actual variations of current

Fig. 83 *a*.

or potential-difference are much more complicated, and peaked curves, such as the curve  $C$  in the figure, are common. For some purposes—are lighting for instance—a flat topped wave-form is most efficient, while in other cases—such as that of transformers—a peaked curve has advantages. Hence arises the importance of the oscillograph, which enables us to follow the wave-form, and actually trace out its curve.

In the chapter on the properties of the dielectric medium, we learnt that the path of the energy by which a current is maintained lies through the dielectric medium. The line of the current represents merely the path along which that energy is degraded into heat by something analogous to a frictional slip. Hence, when the energy is alternating in character, successive currents spread into the conductor in opposite directions—spread in with a finite velocity, just as heat is conducted into the ground under the alternating temperatures of day and night, summer and

winter. Moreover, just as the quick alternations due to day and night become insensible at a small distance from the surface of the ground, while the slower alternations due to the varying seasons penetrate deeper, so a quickly alternating current will only reach a small distance into the substance of a conductor. This limitation of an alternating current to the outer layers of the conductor may be regarded as an explanation of the increased effective resistance of the conductor when a continuous is replaced by an alternating current.

The quantitative theory of the subject may be investigated by observing that the self-induction of a current flowing along the outer strata of a conductor is less than that of a current flowing within. The magnetic force inside a cylindrical tube carrying a current may be shown to vanish. Hence currents flowing down the outside of a wire produce no magnetic field within, and no induced currents. Thus the inertia of the current will be less if the current flows through the outside layers only.

The analogy between self-induction and inertia may be pushed farther than we have yet indicated. The dynamical inertia of a body, which measures its mass  $m$ , tends to prevent any change in the velocity  $v$ . The self-induction  $L$  of a circuit tends to prevent any change in the strength  $c$  of current. Hence work must be done in starting or stopping a current, just as it is in starting or stopping a moving body. The work in the latter case is equal to the kinetic energy  $\frac{1}{2}mv^2$ . Thus, on the analogy we are considering, an amount of work  $\frac{1}{2}Lc^2$  is needed to start or stop a current  $c$  in a circuit possessing self-induction  $L$ , and the current, when flowing, must consequently possess an amount of kinetic energy equal to  $\frac{1}{2}Lc^2$ .

A still more complete analogy may be traced by writing down the equations of motion of a body with a velocity accelerating under the action of a force  $F$ , and retarded by a frictional resistance which is proportional to the velocity. If  $v$  be the velocity, and  $R$  the resistance for unit velocity, we have

$$F = m \frac{dv}{dt} + Rv.$$

Now let us compare this equation with that for an electromotive force  $E$  applied to a circuit of resistance  $R$  and self-induction  $L$ . If  $c$  be the current,

$$E = L \frac{dc}{dt} + Rc.$$

Thus the analogy appears to be complete.

**56 a.** Important results follow from the analogy between self-induction and inertia. If a mass  $m$  hanging by a spiral spring be pulled down from its position of equilibrium and let go, it performs a series of vertical oscillations, till the resistance to its motion brings it to rest. If the resistance be small, the oscillations will continue for some time; they will be isochronous, and have a periodic time of  $2\pi\sqrt{m/F_1}$ , where  $F_1$  denotes the force of restitution exerted by the spring when the displacement of the body is unity. Now, as the body oscillates from the middle of its path to one of the ends, the energy changes from the kinetic form to the potential. If  $x$  be the final displacement, the final force of the spring is  $F_1x$ ; the mean force throughout the extension is  $\frac{1}{2}F_1x$ , and the work done, or the final potential energy of the spring, is  $\frac{1}{2}F_1x^2$ .

Now let us consider the analogous case of two parallel plates charged with opposite kinds of electricity. If connexion be made between the plates by means of a conducting wire, an electromotive force acts along it, and a current is set up. If the circuit of the wire possesses appreciable self-induction, the current will possess inertia, and, unless the frictional resistance is very great, the current will tend to flow on, after the condition of equilibrium is reached. The plates will thus acquire reversed charges; the electromotive force will act in the other direction; and electric oscillations will result.

The potential energy of the charged plates is  $\frac{1}{2}eV$ , where  $V$  is the difference of potential, and  $e$  the charge on one plate. If  $C$  be the electrostatic capacity of the system,  $C = e/V$ , and the potential energy is  $\frac{1}{2}e^2/C$ . Now on the analogy of the oscillating spring, the displacement of electricity from its condition of equilibrium, that is the charge on the plate, corresponds with the displacement from its position of equilibrium of the body hanging by the spring.

Corresponding with  $F_1$ , the coefficient of  $\frac{1}{2}x^2$  in the expression for the potential energy of the spring, we have  $1/C$ , the coefficient of  $\frac{1}{2}e^2$  in the expression for the potential energy of the charged plates.

We may now use our analogy to write down the expression for the period of oscillation of the electric system. The self-induction  $L$  of the circuit is analogous to  $m$ , and  $1/C$  to  $F_1$ . The period of the spring is  $2\pi\sqrt{m/F_1}$ , and the corresponding expression is  $2\pi\sqrt{LC}$ .

If the resistance exceed a certain limit, no oscillations will arise. The charges will neutralize each other by means of a steady current, just as the body on the end of the stretched spring will creep slowly to its position of equilibrium if the whole system be immersed in some very viscous liquid.

The interest of these electric oscillations is very great. The discharge from a Leyden jar, the lightning flash itself, will, it is evident, in the right circumstances, produce, not a direct current, but a series of electric oscillations. The periods of such oscillations will be very rapid, perhaps rising to hundreds of thousands per second, and rapidly alternating currents, as we have seen, show preferences for different paths very unlike the preferences shown by steady currents. A lightning flash or a discharge from a jar may take a short cut through air rather than go round a metallic circuit of appreciable self-induction. Hence the necessity of avoiding bends and turns in lightning rods.

The oscillations in the spark from a Leyden jar were first verified by direct experiment by Feddersen in 1857, who analysed the spark by viewing it in a mirror rotating very rapidly. The image was drawn out into a band with bright and dark spaces. On placing a high resistance in circuit, the alternations disappeared, and the image became a band gradually fading away at one end.

The periodic character of the discharge from a Leyden jar may also be demonstrated by another beautiful experiment, due to Professor J. J. Thomson. The discharge is made to pass round a coil of a few turns of insulated wire within which is placed a glass bulb containing air at a low pressure. The alternating currents in the coil induce high electromotive forces in the exhausted air, just as they would do in a secondary circuit in the neighbourhood. By this means the resistance of the air is broken down, and a circular current passes in the form of a luminous ring discharge within the

bulb. The method has been of service in eliminating the effects of the electrodes in the spectroscopic study of electric discharge through gases.

57. Faraday's discovery of electromagnetic induction has proved to be the foundation of a vast industrial development: almost all electrical machinery of practical importance depends on the induction of currents.

Electro-magnetic machinery. An analogy, of great use in designing electromagnetic machinery, may be traced between the permeability of iron and the specific conductivity of an electric conductor. If a bar of iron of uniform cross-section  $A$  be placed in a uniform field of magnetic force of intensity  $H$ , the total number of lines of induction through the iron is  $HA\mu$ . This quantity is known as the flux of induction, and may be written as  $N$ .

$$\text{Now} \quad N = \frac{Hl}{\frac{l}{A\mu}},$$

and we may compare this equation with that expressing the strength of an electric current  $c$ , which is equal to the electromotive force  $E$  divided by the resistance  $R$  of the conductor, or

$$c = \frac{E}{R}.$$

In these two equations, the quantity  $Hl$  corresponds with the electromotive force, and may be called the magnetomotive force; the quantity  $l/A\mu$  corresponds with the electric resistance, and may be called the magnetic reluctance.

The electric resistance is equal to the specific resistance of the material into the length of the conductor divided by the area of cross-section, and, if the reciprocal of the specific resistance, or the specific conductivity, be denoted by  $y$ , we have for the total resistance  $l/Ay$ . Thus  $\mu$  is analogous to  $y$ , except in so far as  $\mu$  is not constant, but depends on the magnetomotive force.

The total resistance of an electric circuit is the sum of the individual resistances of its parts, and the total reluctance of a magnetic circuit is the sum of the reluctances of the different parts, whether iron or air, which together complete the circuit.

When the approximate value of  $\mu$  which corresponds with the

magnetic fields to be used in a machine is known, this law of the magnetic circuit enables us to calculate the number of "ampere-turns" needed in winding and exciting the electro-magnets.

58. In dynamos, coils of wire wound on iron shuttles or rings are rotated in the fields of strong electro-magnets, excited either separately by an independent machine, or by the current they themselves induce in the rotating coils.

The principle of the dynamo is best explained by a diagram such as Figure 84. Let  $CC'$  be a circular coil of wire, spinning in a magnetic field where the lines of induction run in the direction of the arrow  $AB$ . When the plane of the coil lies along  $AB$ , no lines of induction pass through it. As the coil spins clockwise through  $90^\circ$ , the number of lines threading it continually increases and reaches a maximum at  $EF$ . From  $EF$  onwards through  $90^\circ$ , the number decreases. Consequently, the

Fig. 84.

induced electromotive force is reversed as the coil passes through the position  $EF$ , at right angles to the lines of induction. When the coil again lies along  $AB$ , no lines thread it, and, as it rotates through the third quadrant, the number again increases. But now they enter the other face of the coil, and must be counted as negative. The present increase, then, produces an electromotive force in the same sense as did the decrease in the second quadrant, and no change of sign occurs in the electromotive force when the coil passes the line  $AB$ , that is, when its plane lies along the direction of the lines of induction. The negative lines, however, will begin to decrease when  $EF$  is again passed. Thus the electromotive force in the coil changes sign whenever the coil passes the position where its plane is normal to the magnetic field.

By connecting the ends of the coil with brass pieces on an insulating drum which rotates with the coil, the currents may be

led away through wire brushes to the external circuit. By proper arrangements, either alternating currents may be obtained, or the alternating currents in the coil may be commutated and passed always in the same direction round the external circuit. In practice, many coils are wound on the same armature, so that nearly continuous currents may be obtained; and the substance of the armature is iron, so that the induction through it is increased in the ratio of the magnetic permeability of iron to that of air.

An elementary and simplified theory of the dynamo enables us to obtain a quantitative expression, approximately accurate, for the average value of the current. Let  $N$  denote the total number of lines of magnetic induction which traverse the coil when normal to the lines of force. Then  $-N$  must be the number through it when turned through  $180^\circ$ , so that it lies again normal to the field with its faces reversed. The total change of induction is thus  $2N$  during one half-revolution. If  $t$  be the time occupied in this half-revolution, the average rate of change of induction is  $2N/t$ , and this measures the average induced electromotive force. If we neglect the change of sign of the current, or if we commutate the current so that it always passes in the same direction in the external circuit, we may calculate its average value by dividing the average electromotive force by  $R$  the total resistance of the circuit, including both that in the coil and that without. If  $x$  be the number of revolutions of the coil per second,  $t$ , the time of one half-revolution, is  $1/2x$ , and thus the average current  $\bar{c}$  is given by

$$\bar{c} = \frac{4Nx}{R}.$$

If the total area of the coil, including the area of each of its windings, be  $A$ ; and if  $B$  be the magnetic induction in the field, assumed uniform, then

$$\bar{c} = \frac{4ABx}{R}.$$

In alternating current machines, the field-magnets must be excited separately. In direct current dynamos, they may be excited by the current of the machine, by connecting the coils of the field-magnets either in series (Fig. 85) or as a shunt

(Fig. 86) with the external circuit. In the shunt-wound machine, an increase of external resistance throws more current through the

Fig. 85.

Fig. 86.

magnet coils, and thus increases the induced electromotive force. In series wound machines, by increasing the external resistance we diminish the current everywhere, and thus decrease the induced electromotive force. By a proper combination of shunt and series coils on the field magnets, it is possible to secure a constant electromotive force, whatever be the resistance of the external circuit.

The mechanical force acting on a current in a magnetic field is used to obtain mechanical power in electric motors. If a current be passed through the armature of a dynamo in the reverse direction to that of the current the machine itself will yield, it is evident that the armature will tend to rotate. At starting, a large current will pass, but, as the speed increases, a back electromotive force is set up by the usual action of the machine, and the current taken by the motor diminishes. Any dynamo will act as a motor, though the most convenient mechanical arrangements usually differ for the two purposes.

**Transformers and induction coils.** 59. The power conveyed by an electric circuit, that is, the work done per second, is the product of the electromotive force and the current, or  $Ec$ . Thus, by increasing  $E$ , it is possible to convey a large amount of power by the use of a small current. The conductor required to carry the current with a certain percentage of heat-loss must possess an area of cross-section proportional to the current, and copper is very expensive. Hence it is economical to generate the current by a high tension dynamo, and convert the power into currents of a safe voltage near the consumer by means of an apparatus called a transformer.

In this instrument, two coils, one of few turns of thick wire, and one of many turns of thin wire, are wound on a core of iron wires or strips, which may either be straight or in the form of a continuous ring. An alternating current of high voltage is passed round the coil of many turns. The magnetism of the core is continually reversed by the alternating current, and the lines of induction through the other coil are reversed continually also. An induced electromotive force, proportional to the number of turns of wire, is obtained, and, as the resistance is low, a large current results. It is obvious that the power of the secondary current cannot exceed that of the primary, and we have as the limit of efficiency

$$E_1c_1 = E_2c_2.$$

If the circuit of the secondary coil be not completed, no current flows round it, and no power is taken from the transformer. We should suspect that in these conditions less power is taken from the primary circuit. This is found to be the case, and the reason is clear in the light of what was said on page 153. The presence of a closed secondary circuit in the neighbourhood decreases the effects of self-induction in the primary, and enables more current to pass through it. When the secondary circuit is broken, the primary acts as a choking coil (p. 157), and very little current flows, owing to the reverse electromotive force of self-induction.

The induction coil, invented by Ruhmkorff, may be classed as a transformer (Fig. 87). It enables us to obtain an intermittent current of high electromotive force from the direct current given by a few voltaic cells. Two coils are wound on an iron core made

of a bundle of soft iron wires to reduce the loss by eddy currents, which would circulate extensively in a solid core. The inner coil is made of a few turns of thick wire, and the outer coil of an immense number of turns of very fine wire wound in sections,

Fig. 87.

most carefully insulated, and so arranged that turns with high differences of potential are separated widely from each other. The primary current, which passes round the inner coil, is interrupted at frequent intervals of time. As a simple means of effecting this, the arrangement used in electric bells may be adopted. The primary current is made to pass from a platinum stud fixed to a spring into a platinum point in contact with it. To the end of the spring is attached a piece of soft iron, which lies near one end of the iron core of the coil. When the current passes, the core is magnetized, and attracts the piece of soft iron. The spring is pulled away from the point, and the circuit is broken. The spring then flies back, making contact with the point, and the current is established once more.

An electrolytic interruptor was invented by Wehneltdt, who found that, if the primary current were passed through a solution of dilute sulphuric acid, the electrodes being a platinum point and a platinum plate, rapid interruptions occurred spontaneously. The

action of this apparatus is not fully understood. It may depend on sudden evolutions of gas at the electrodes.

By some such automatic arrangement, the primary current is made and broken rapidly, and a series of alternately directed electromotive forces are set up in the secondary coil. Since all the tubes of magnetic induction produced by the primary current must thread all the turns of the secondary circuit, the induced electromotive force is very large. Such a coil, then, would furnish an alternating current in the secondary circuit. By the use of a condenser, however, we may increase the electromotive force which arises in the secondary circuit when the primary current is broken. The condenser is made of intervening sheets of tin-foil and paraffined paper, the alternate sheets of foil being connected together. Its opposite systems of plates are connected one with each side of the contact-breaker: in the usual form, one with the platinum point and one with the spring. When the point is in contact with the spring, the condenser is discharged and the core is magnetized. When the point separates, the condenser is charged through the primary coil, the process taking place by a series of electric oscillations which rapidly demagnetize the iron core. By this means the flux of induction through the coil is destroyed much more sharply than it would be in the absence of a condenser, and the electromotive force on breaking the current is increased greatly.

The use of induction coils has extended considerably of late, owing to their employment in hospitals for the production of Röntgen rays, and their application to many of the more recent branches of physical research.

## CHAPTER VIII.

### ELECTRICAL UNITS.

The units of physical measurement. Electrostatic and electromagnetic units.

The determination of a current in absolute measure. The determination of a resistance in absolute measure. The determination of an electromotive force in absolute measure. Other practical units.

60. PHYSICAL science is based on the perceptions of our senses, and the quantities with which we deal in studying that branch of knowledge are based, more or less directly, on such sense-perceptions. In measuring a physical quantity, two factors are necessary. We must choose and define some unit of the quantity, and we must determine how many times that unit is comprised in the quantity we wish to measure.

The ideas of length and time may be regarded as primary—length as the simplest form of our conception of space, time as a recognition of sequence in our states of consciousness. It is usual to take mass as a third fundamental quantity. Whether mass is to be considered as truly a primary conception, is still a matter of controversy. In the view of the present writer, the third primary conception is that of force, which we derive from our muscular sense when pushing or pulling. Equal masses are then defined as masses in which equal forces produce equal accelerations, and unequal masses are in the inverse ratio of the accelerations so produced.

The conception of mass, whether it is primary or derived from that of force, is soon found necessary in the mental picture which

the study of dynamics enables us to make of the world around us. The great convenience of the conception of mass arises from the fact that, in any system, the quantity so named is found to remain constant throughout a series of dynamical changes. On account of this principle of the conservation of mass, it is well to take mass as the third fundamental physical quantity, and base our system of units on those of length, time and mass.

These fundamental units must be selected arbitrarily. In civilised countries, the unit of length is taken as the length between two marks on a certain standard metallic bar. In England there is a standard yard, and in France a standard metre. In point of fact, both these units are selected arbitrarily for their convenience, though the original idea of the metre was derived from a connexion with the supposed dimensions of the earth. For scientific purposes, the hundredth part of the metre, or centimetre, is taken as the unit of length.

Like the unit of length, the unit of time is arbitrary, and for the convenience of daily life the obvious unit to select is the day, while the sequence of the seasons suggests another equally arbitrary unit, the year. The exact relation between these two units can only be determined by careful astronomical observation. Again, for laboratory use, a smaller unit is convenient, and the second, a certain fraction of the astronomical unit, is chosen.

The unit of mass, whether pound or kilogramme, likewise, is fixed arbitrarily, and defined as a mass equal to that of a standard kept at some Government Office, though the original kilogramme was made as nearly equal as was then possible to the mass of one cubic decimetre of water. Once more, a smaller unit is convenient in the laboratory, and the thousandth part of the kilogramme, or gramme, has been chosen. The system of units based on the centimetre, the gramme, and the second, is in almost universal use for scientific purposes, and may be referred to as the C.G.S. system.

All other dynamical units may be derived from these three fundamental units of length, time, and mass. Thus, the unit of velocity is the velocity of one centimetre per second, and that of acceleration means unit increase of velocity per second, or the

acceleration of one centimetre per second per second. The definition of mass (p. 171) gives us the relation

$$\text{mass} = \text{force}/\text{acceleration},$$

and, therefore, taking mass as our fundamental unit for the sake of using a constant quantity, we see that the unit of force, in the C.G.S. system called the dyne, is that force which produces unit acceleration when acting on unit mass. We may express this result in the form

$$[\text{Force}] = M[\alpha] = MLT^{-2},$$

a relation that gives us the physical dimensions of force in terms of the three fundamental units. Also we see that the dimensions of work or energy are given by the relation

$$[\text{Work}] = ML^2T^{-2}.$$

61. When we pass to the consideration of electrical quantities,

Electrostatic  
and electro-  
magnetic  
units.

we find that, in the present state of science, we cannot express them completely in terms of dynamical units.

It is possible that some day this may be done, but, when the necessary relation has been discovered, it will not follow that it is better to express electrical quantities in terms of those of dynamics. It may turn out to be quite as correct philosophically to express dynamical units in terms of electricity, though the absence of any special electrical sense may make such a proceeding less convenient and satisfying to the human mind. It should be pointed out, however, that, to the electrical fish or torpedo, electric intensity may be a direct sense-perception, and quite as real as mechanical force.

On the electrostatic system of units, we ought strictly to define unit charge of electricity by means of the experimental relation given on page 23,

$$F = \frac{e_1 e_2}{kr^2},$$

where  $F$  is the mechanical force between two quantities  $e_1$  and  $e_2$  of electricity, which as point-charges, are placed in a medium of dielectric constant  $k$  at a distance  $r$  from each other.

Hence, the dimensions of quantity of electricity on the electrostatic system are

$$[e] = M^{\frac{1}{2}} L^{\frac{3}{2}} T^{-1} k^{\frac{1}{2}},$$

and involve the unknown dimensions of the specific inductive capacity or dielectric constant of the medium, though the conventional unit is defined on the supposition that this unknown quantity has no dimensions.

In a similar manner, we may deduce the dimensions of the other electrostatic units, and tabulate them as follows:

Dielectric constant	$k$	$k$
Quantity of electricity	$e$	$M^{\frac{1}{2}} L^{\frac{3}{2}} T^{-1} k^{\frac{1}{2}}$
Electric intensity	$f$	$M^{\frac{1}{2}} L^{-\frac{1}{2}} T^{-1} k^{-\frac{1}{2}}$
Potential difference	$V$	$M^{\frac{1}{2}} L^{\frac{1}{2}} T^{-1} k^{-\frac{1}{2}}$
Capacity	$C$	$Lk$
Electrostatic polarization	$P$	$M^{\frac{1}{2}} L^{-\frac{1}{2}} T^{-1} k^{\frac{1}{2}}$
Current ( $=e/\text{time}$ )	$c$	$M^{\frac{1}{2}} L^{\frac{3}{2}} T^{-2} k^{\frac{1}{2}}$
Strength of magnetic pole ( $=\text{force}/\text{current}$ )	$m$	$M^{\frac{1}{2}} L^{\frac{1}{2}} k^{-\frac{1}{2}}$
Magnetic force	$H$	$M^{\frac{1}{2}} L^{\frac{1}{2}} T^{-2} k^{\frac{1}{2}}$
Magnetic permeability	$\mu$	$L^{-2} T^2 k^{-1}$

The electromagnetic system of units should, in like manner, be based on the expression for the force between two magnetic poles placed in a medium of magnetic permeability  $\mu$ , at a distance  $r$  from each other:

$$F = \frac{m_1 m_2}{\mu r^2},$$

though, in our conventional definitions we agree to ignore the unknown dimensions of the magnetic permeability of the medium.

Unit current is defined as equivalent to magnetic shell of unit strength, which itself has unit magnetic moment per unit area. The derivation of the other units which are tabulated below will be clear.

Magnetic permeability	$\mu$	$\mu$
Strength of magnetic pole	$m$	$M^{\frac{1}{2}} L^{\frac{3}{2}} T^{-1} \mu^{\frac{1}{2}}$
Magnetic force	$H$	$M^{\frac{1}{2}} L^{-\frac{1}{2}} T^{-1} \mu^{-\frac{1}{2}}$
Magnetic potential	$V'$	$M^{\frac{1}{2}} L^{\frac{1}{2}} T^{-1} \mu^{-\frac{1}{2}}$
Magnetic induction	$B$	$M^{\frac{1}{2}} L^{-\frac{1}{2}} T^{-1} \mu^{\frac{1}{2}}$
Current	$c$	$M^{\frac{1}{2}} L^{\frac{1}{2}} T^{-1} \mu^{-\frac{1}{2}}$
Quantity of electricity (= current $\times$ time)	$e$	$M^{\frac{1}{2}} L^{\frac{1}{2}} \mu^{-\frac{1}{2}}$
Electric potential-difference or electromotive force	$V$ or $E$	$M^{\frac{1}{2}} L^{\frac{3}{2}} T^{-2} \mu^{\frac{1}{2}}$
Electric capacity	$C$	$L^{-1} T^2 \mu^{-1}$
Dielectric constant	$k$	$L^{-2} T^2 \mu^{-1}$

Thus, in each system of units, the unknown dimensions of a property of the dielectric medium are involved—its specific inductive capacity on the one side, and its magnetic permeability on the other. The accepted definitions of the various units ignore these unknown quantities, and treat  $k$  and  $\mu$  as numbers having no dimensions—as mere ratios, giving the value of the quantity in terms of that of air. The unit of electric charge, for instance, is defined as that quantity of electricity which repels an equal similar quantity with the force of one dyne when each of the two quantities is placed as a point-charge in air, at a distance of one centimetre from the other.

We now see that, by ignoring the unknown dimensions of  $k$  and  $\mu$ , it is possible to arrive at a definition of any electrical or magnetic quantity by two distinct methods. Two distinct units result—units different in dimensions and different in magnitude, the difference arising from the assumption that  $k$  and  $\mu$  have no dimensions. Let us take for example, the unit of current. On the electrostatic system, the idea of current is derived from that of electric charge—unit current flows through a conductor when unit charge passes through it at a uniform rate in unit time. On the electromagnetic system, on the other hand, a current is detected, defined and measured by means of its magnetic effects; the conception of a quantity of electricity is now derived from that of current. The electromagnetic unit of current is the current which is equivalent to a magnetic shell of unit strength, or the

current which produces a magnetic force equal to  $2\pi/r$  at the centre of a circular path of radius  $r$ . By either of these definitions, we obtain a unit of current different from that derived from the electrostatic system. The electrostatic dimensions of current, as usually defined, are those of quantity of electricity divided by time, or  $M^{\frac{1}{2}}L^{\frac{3}{2}}T^{-2}$ , while the electromagnetic dimensions are  $M^{\frac{1}{2}}L^{\frac{1}{2}}T^{-1}$ . Thus, the units of current as ordinarily defined, possess different dimensions on the two systems, and the ratio of the dimensions of the electrostatic to those of the electromagnetic unit is

$$\frac{M^{\frac{1}{2}}L^{\frac{3}{2}}T^{-2}}{M^{\frac{1}{2}}L^{\frac{1}{2}}T^{-1}} = LT^{-1}.$$

Now,  $LT^{-1}$  is the dimensions of a velocity. Hence, the ratio of the electrostatic to the electromagnetic unit of current involves the dimensions of a velocity.

Again, on the electrostatic system, the dimensions of capacity, namely, quantity of electricity divided by potential-difference, are simply those of length,  $L$ , while, on the electromagnetic system, they are  $L^{-1}T^2$ . Here the ratio of the units, electrostatic to electromagnetic, involves  $L^2T^{-2}$ , that is, the square of a velocity.

These discrepancies between the units of one and the same quantity depend, as we have seen, on the assumption that the specific inductive capacity and the magnetic permeability of the electromagnetic medium are mere ratios—quantities of no physical dimensions, expressing the property of the medium simply as compared with the same property of air. If, instead of thus ignoring the dimensions of  $k$  and  $\mu$ , we keep these symbols, unknown as they are, in our definitions, we may assume that the same quantity, however defined, will possess the same dimensions. Taking for instance the two definitions of unit current, we have

$$M^{\frac{1}{2}}L^{\frac{3}{2}}T^{-2}[k]^{\frac{1}{2}} = M^{\frac{1}{2}}L^{\frac{1}{2}}T^{-1}[\mu]^{-\frac{1}{2}}.$$

Thus,

$$[k]^{\frac{1}{2}}[\mu]^{\frac{1}{2}} = L^{-1}T,$$

and a similar result is reached whatever pair of units we consider.

Hence, although the individual dimensions of the two quantities, the dielectric constant and the magnetic permeability, remain

unknown, it follows that the dimensions of their product are determined, and are given by the relation

$$[k\mu] = \frac{1}{v^2}.$$

To this important result we shall return later; our immediate concern is with the methods of determining experimentally the values of different electrical quantities in the absolute electrostatic or electromagnetic units defined on the assumption that  $k$  and  $\mu$  are quantities having no dimensions.

**62.** The definition of unit current as equivalent to a magnetic shell of unit strength has been shown in § 41, Chapter V, to lead to the same results as a more practical definition, which makes the unit current that current which, when flowing round a circle of radius  $r$ , produces a magnetic force of  $2\pi/r$  at the centre. From this definition we deduced the theory of the tangent galvanometer, and showed that, with proper precautions, that instrument gave a fairly accurate means of determining the electromagnetic value of a current. Unfortunately, this method involves a knowledge of the horizontal component of the earth's magnetic force; and, not only is the accurate determination of this quantity a long and laborious undertaking, but the continual variations of its value make it necessary to record its changes throughout the time of the experiments. This objection applies, it is true, to some of the further methods now to be discussed, but others, less affected by the difficulty, have been devised.

One such method depends on the measurement by weighing of the force between circuits when currents flow round them. Practical instruments have been devised by Lord Kelvin and others for the measurement of currents by means of such forces. In these instruments, two small moveable coils are attached one to each end of the beam of a balance. Each of the moveable coils lies between and parallel to two larger fixed coils of approximately equal size, round which the currents pass in such a direction that the force on one moveable coil acts upwards and

the force on the other coil acts downwards (Fig. 88). A pointer at the end of the beam shows when it is horizontal, and a sliding weight can be adjusted to bring the beam back to this position when it is deflected. The couple tending to deflect the beam

Fig. 88.

varies as the square of the current, while that tending to restore the beam to its position of equilibrium varies as the displacement of the sliding weight. Hence the current is proportional to the square root of the distance between the weight and the fulcrum.

The beam is graduated according to this square root scale, and, if we know the absolute value of the graduations, the instrument

Fig. 89.

may be used as a standard of reference. It is called an ampere-balance.

For our present purpose of investigating the absolute electromagnetic value of some current which can afterwards be recovered, we must calculate the couple on the moveable coils from the dimensions and arrangement of the apparatus. We have seen, § 41,

that the magnetic force on the axis of a large circular current not far from its centre is fairly uniform over a considerable space, and equal to  $2\pi n_1 c r_1^2 / (r_1^2 + x^2)^{\frac{3}{2}}$  where  $c$  is the current,  $n_1$  the number of turns of wire,  $r_1$  the radius of the coil, and  $x$  the distance of the point on the axis from the centre of the coil. We may use this result to calculate the coefficient of mutual induction between a large coil and a small coil with parallel planes, the two coils being co-axial. The coefficient  $M$  is the number of tubes of magnetic induction threading the total area  $n_2 \pi r_2^2$  of the small coil when unit current circulates in the large coil. It will therefore have the value

$$n_2 \pi r_2^2 \cdot 2\pi n_1 r_1^2 / (r_1^2 + x^2)^{\frac{3}{2}}$$

or

$$2\pi^2 n_1 n_2 r_1^2 r_2^2 / (r_1^2 + x^2)^{\frac{3}{2}}.$$

Now we have seen that the mutual potential energy of two circuits, when unit current passes through both, is measured by their coefficient of mutual induction. The force on a body in any direction is equal to the rate of decrease of the potential energy as the body moves in that direction. Hence, the mechanical force  $F$  on the small coil in the position we have described, tending to move it towards the large coil when a current  $c$  flows round both coils, is  $-c^2 dM/dx$ . Thus

$$F = 6\pi^2 n_1 n_2 r_1^2 r_2^2 \frac{x}{(r_1^2 + x^2)^{\frac{5}{2}}} c^2.$$

If the plane of the small coil coincide with that of the large one, so that  $x$  is nothing, there is no force tending to change  $x$ , while at a great distance also the force vanishes. Hence there is some position for the small coil where the attraction is a maximum; the force is then independent of small errors in the value of  $x$ . In these circumstances, there is a fixed relation between  $x$  and  $r$ , and the result may be shown to depend on the ratio of the effective radii of the large and small coils, not on the absolute values of those radii. Now the ratio of the radii may be found by measuring electrically the ratio of the galvanometer-constants of the two coils, a quantity which can be obtained much more accurately than the effective radius of a number of turns of wire wound in a coil.

The approximate theory of the subject given above assumes that each coil may be treated as a circle, the dimensions of the channel for the wires being supposed negligible compared with the radius of the circle. This, of course, is very far from being the case, and the exact theory of the apparatus is somewhat complicated. Nevertheless, the investigation we have given serves to illustrate the principles involved.

The method was used by Lord Rayleigh and Mrs Henry Sidgwick in 1884 for the determination of a current in absolute measure. The small coil was suspended from one arm of a balance, the current being taken in by means of flexible leads of fine copper wire. The large coil, as in the ampere-balance described above, was doubled; one large coil was placed on each side of the small coil, and the current was sent opposite ways round the two large coils. The force was thus doubled, and the magnetic field of force made more uniform.

When a resistance has been determined in absolute measure, it is possible to construct a standard resistance coil and keep it for future reference. No such possibility, however, exists in the case of a current. To determine a certain current in absolute measure might be of interest to the experimenter at the time, but it would be of no use for future reference. It is necessary, at the time of the absolute determination, to measure the same current in some practical way, which may afterwards be repeated with other currents, in order to obtain an indirect measurement of those currents in absolute units.

One property of a current, which has often been used for this purpose, is its power of depositing a metal from the solution of one of its salts. This process will be studied in the chapter on electrolysis. Here it is enough to say that the amount of silver deposited from a solution of silver nitrate by a given current flowing for a given time, that is, by the passage of a given quantity of electricity, is a quantity which, within the limits of experimental accuracy, seems to be quite constant. The mass of silver deposited, then, may be used as a measure, not directly indeed of the current passing at any particular instant, but of the total electric transfer round the circuit during the time of

the observation. If, however, the current be maintained constant throughout, its value at any instant will be proportional to the mass of silver divided by the time.

The experiments of Lord Rayleigh and Mrs Sidgwick went to show that one electromagnetic unit of electricity, when passed through a solution of silver nitrate from a plate of silver to the surface of a platinum bowl, deposited 0·0111795 gramme of silver. Many later experiments have been made, with the result that the mean of the best observations indicates that the true figure is probably between 0·01118 and 0·01119. The ampere, or practical unit of current, is one-tenth of the electromagnetic unit, and has been defined for practical purposes by the International Congress which met at Chicago in 1893 as that current, which, flowing through a solution of silver nitrate, deposits 0·001118 gramme of silver per second. This is now the legal definition of the ampere, and it is possible that, even should future research show that the electromagnetic unit is appreciably different from the value taken at present, no change would be made in the practical definition of the ampere. The supposed dimensions of the earth, assumed for the original construction of the standard metre by the reforming zeal of the first French Republic, have been shown by later determinations to be erroneous; but the distance between two marks on the French standard bar then made continues to be the legal metre.

Another method, for the determination of currents in absolute measure, depends on the use of an instrument known as Weber's electrodymanometer. Two large circular coils are mounted with their planes parallel and vertical, the coils being coaxial. They may be looked upon as part of a double-coil tangent galvanometer. Instead of the needle, however, a smaller coil is hung by a bifilar suspension at the middle of the line joining the centres of the two coils. The plane, of the small coil when in its position of equilibrium, lies at right angles to the planes of the two large coils. A current is passed in series through the two large coils, and, by means of the bifilar suspension, through the small suspended coil, which then tends to set with its plane parallel to those of the large fixed coils, as may be seen by

considering the direction of the axis of the equivalent magnetic shell.

The couple of restitution due to the bifilar suspension is approximately proportional to the sine of the angle of deflection, and may be determined by experiment: for a deflection  $\theta$  let us call it  $b \sin \theta$ . The couple due to the current is

$$\frac{2\pi n_1}{r_1} cM \cos \theta,$$

where  $M$  is the magnetic moment of the suspended coil. The strength of the current is measured by the strength of the equivalent magnetic shell, and the strength of a shell is the magnetic moment per unit area. Thus, the effective area of the suspended coil being  $\pi r_2^2 n_2$ , its magnetic moment is  $\pi r_2^2 n_2 c$ . We therefore have

$$\frac{2\pi n_1}{r_1} c\pi r_2^2 n_2 c \cos \theta = b \sin \theta,$$

or

$$c^2 = \frac{br_1}{2\pi^2 r_2^2 n_1 n_2} \tan \theta.$$

When a current flows in the suspended coil, the coil tends to set in the earth's field, and the couple due to this tendency must be added to that of the bifilar suspension. Corrections are also necessary for the finite size of the windings, and other differences between the practical apparatus and the simplified form of it contemplated by the elementary theory given above.

It should be noted that the deflection depends on  $c^2$ , so that the electro-dynamometer may be employed for alternating currents.

**63.** The three quantities, current, electromotive force, and resistance, are connected together by the well-known relation described by Ohm's law. Hence the electrical quantities involved in the passage of a steady current are all determined in absolute electromag-

The determination of a resistance in absolute measure.

netic measure if the values of two of these three quantities are known. We have described methods of determining the strength of a current, and it remains to consider the second type of experi-

ment, whereby the solution of the problem is completed. The experiments give values both of the electromotive force and also of the resistance, since, when the current is known, there is a necessary relation between them. But, since permanent resistance coils are easy to construct, it is usual to regard the experiments as an investigation of a resistance in absolute measure, or, as the phrase goes, the determination of the ohm.

The first determination of the resistance of a wire in absolute electromagnetic measure was made by Kirchhoff, who calculated from their dimensions the coefficient of mutual induction of two coils when in a certain relative position, and observed the throw of a galvanometer when one coil was moved quickly into a position where the mutual induction was zero.

Joule's calorimetric experiments on the heat developed by a current (see page 132) give a value for the work done by a current when passing through a certain resistance. The current may be measured in electromagnetic units by means of a tangent galvanometer or otherwise, and the observed thermal effect then gives the absolute value of the electromotive force and the resistance between the ends of the coil immersed in the calorimeter.

The first determination, on which was based an extensive manufacture of resistance coils, was undertaken at the instance of the British Association, and was carried out by Balfour Stewart, Fleeming Jenkin, and Clerk Maxwell in 1863.

In order to understand the principles involved, let us consider the case of a coil of wire, spinning round a vertical axis in the earth's magnetic field of force. The plane of the coil being vertical, the vertical magnetic component will not be involved, and may be neglected; the horizontal component alone need be taken into account. As we saw in § 58, when considering the theory of the dynamo, a periodic electromotive force is set up in the coil, the direction being reversed twice in each complete revolution, when the plane of the coil lies at right angles to the lines of induction. An alternating current will circulate in the coil; it will have a periodic time equal to that of the electromotive force, and, owing to the small self-induction of the coil, will not lag appreciably behind the electromotive force in phase.

An alternating current of quick period will not affect an ordinary galvanometer. By leading off the current into an external circuit through a rectifying commutator, as described on page 165, its average value might be determined by a tangent galvanometer. But such a measurement could give only a roughly accurate result, and another method was adopted.

If a compass-needle be suspended at the centre of the coil itself, the position of the coil relative to that of the needle will be reversed periodically in time with the reversals of the current. Thus the couple on the needle due to the current will act always in the same direction, and the needle will suffer a permanent deflection, which is constant if the coil rotate at a constant rate, of which the period is rapid compared with the time of vibration of the needle itself.

The average couple on the needle due to the varying current in the coil may be calculated, and thus its observed deflection may be used to determine the average current in electromagnetic units. It will be noticed that the horizontal component of the earth's magnetic field comes into each side of the equation of equilibrium of the needle; it determines the induced electromotive force in the coil, and the couple tending to deflect the needle; but also it determines the couple tending to return the needle to its original position of equilibrium. Therefore, to a first approximation, the indications of the apparatus are independent of the value of the earth's field. A correction has to be applied, however, for the magnetic field of the needle itself, which of course produces an electromotive force in the spinning coil.

The electromotive force in the coil being thus calculated, and the current being deduced in electromagnetic units from the observed deflection of the needle, the resistance of the coil can be calculated in absolute units, and, by comparison with it, resistance coils of any required value may be constructed. The ohm coils based on the results of these experiments—the B.A. units, as they are often called—for long were the usual standards of resistance. Of recent years, however, more accurate determinations of the ohm, both by the use of spinning coils and by other methods now to be described, have led to the construction of new

standards. The old B.A. unit is 0.9863 of the new or "international ohm."

Perhaps the method which is capable of determining a resistance in electromagnetic units with the greatest precision is that due to Lorenz, and used by him, by Lord Rayleigh and Mrs Sidgwick, and by others, for the redetermination of the ohm.

We have seen (page 149) that, if part of a circuit is moveable, it will tend to travel under the influence of a magnetic field so that the total induction through the circuit is increased. Let us imagine that a metallic disc is mounted to rotate on its axis so that its plane is normal to a magnetic field of known intensity, and that two brushes touch the disc, one at its axis and one at its circumference. If a current be passed through the disc between these brushes, the magnetic force will so act on each element of current that it tends to move in the direction of the circumference of the disc. Thus, on the disc as a whole, there acts a force with a moment about the axis tending to make the disc rotate in its own plane.

Hence it follows that, in the converse case, when no external current is passed through the disc, but the disc is made to rotate by external means in the magnetic field, an electromotive force will be set up in the circuit, consisting of the disc, the brushes, and an external wire joining the brushes.

We may calculate the electromagnetic value of this electromotive force, by considering the work done by the battery which we imagined to maintain the current in the first case; or, more simply, by reckoning the number of magnetic lines of induction cut by the lines of current-flow in the disc when it is made to rotate as supposed in the second case. If  $n$  denote the number of revolutions made by the disc per second, and  $r$  its radius, the area swept out per second by any radius of the disc, and therefore by any line of current-flow, whether straight or curved, will be  $n\pi r^2$ ; and, if  $B$  be the magnetic induction, that is, the number of lines of induction through unit area, the total change of induction per second through the circuit, which measures the induced electromotive force  $E$ , is given by the relation

$$E = n\pi r^2 B = nN,$$

where  $N$  is the total flux of induction through the disc when at rest.

Lord Rayleigh placed the disc between two circular coils through which passed a constant current, the axes of the coils and of the disc being coincident. If, for the moment, we neglect the magnetic field of the earth, which is small compared with that due to the two coils, we see that

$$N = cM,$$

where  $M$  is the coefficient of mutual induction between the coils and the disc, and  $c$  the current passing through them. The electromotive force, due to the rotation of the disc, is now given by

$$E = ncM.$$

The arrangement of apparatus is shown in Figure 90. A galvanometer (1) is placed in the circuit connecting the centre of

Fig. 90.

the disc and the rim, and the electromotive force in this circuit is balanced against that in a certain part  $PQ$  of the main circuit of the two coils, the resistance between  $P$  and  $Q$  being adjusted till no current passes through the galvanometer. If  $R$  be the resistance between  $P$  and  $Q$ , we then have

$$E = Rc = ncM$$

or

$$R = nM.$$

The value of  $M$ , the coefficient of mutual induction between the two coils and the disc, can be calculated from their dimensions and relative positions, and hence we obtain the resistance  $R$  in electromagnetic measure.

In a method used by Mr Glazebrook for the determination of the ohm, the mutual induction between two coils is calculated from their dimensions and relative position, and then determined experimentally by observing the throw of a ballistic galvanometer. The galvanometer is standardised by passing through it a steady current furnished by the electromotive force between two points in the primary circuit.

On the mean result of the best determinations, the International Congress of 1893 re-defined the ohm. One ohm is  $10^9$  electromagnetic C.G.S. units, and, for practical purposes, may be taken as the resistance at the temperature of melting ice, of a column of mercury of uniform cross-section, which, at the same temperature, has a length of 106.3 centimetres, and a mass of 14.4521 grammes. Such a column is, as nearly as possible, one square millimetre in cross-section.

**64.** As we have pointed out already, when the absolute values of a standard current and of a standard resistance are known, that of an electromotive force can be deduced. One method of doing this, used by Mr Glazebrook and Mr Skinner, may briefly be described. The current from a battery of accumulators is passed through a silver voltameter to measure its value in absolute units by reference to the standard determinations. The current also passes through two resistance boxes in series, of which the resistances are known in terms of the standard ohm. The sum of the resistances in the two boxes is maintained constant, so that, if resistances are taken out of one box, equal resistances are put into the other. The current is thus kept constant. If  $R$  be the resistance between the terminals of one box, and  $c$  the current through it, the electromotive force between its terminals is  $Rc$ , and this electromotive force may be balanced directly against that of some constant

The determination of an electromotive force in absolute measure.

cell, such as that of Latimer Clark, by introducing them in opposite directions into the same circuit of a high resistance reflecting galvanometer, and adjusting the resistances in the boxes till there is no deflection. The electromotive force of the Clark's cell is then equal to  $Rc$ , and thus its value is obtained in absolute measure. The cell may afterwards be used as a standard, and the electromotive forces of other cells determined by comparison with it. The comparison may be effected by means of the potentiometer.

The volt is  $10^8$  electromagnetic units, and the Congress of 1893 defined the International Volt as the electromotive force, which, steadily applied to a conductor with a resistance of one international ohm, will produce a current of one international ampere, and represented sufficiently well for practical use by  $1000/1434$  of the electromotive force at  $15^\circ \text{C}$ . between the poles of a Clark's cell prepared according to a standard specification. Since the date of the Congress several new investigations have been made, and it seems possible that the true electromotive force of a Clark's cell is lower by one or two parts in a thousand, and more nearly equal to 1.432 or 1.433 of a volt.

**65.** When the absolute measure of the practical units of current, resistance, and electromotive force are once determined, the values of the practical units of the other electrical quantities follow by definition, and may be determined experimentally by ordinary electrical methods without new absolute measurements. The following definitions were adopted in 1893.

*Quantity.* The International Coulomb is the quantity of electricity transferred by a current of one international ampere in one second.

*Capacity.* The International Farad is the capacity of a condenser charged to a potential of one international volt by one international coulomb of electricity.

*Work.* The Joule is equal to  $10^7$  units of work in the c.g.s. system, and is represented sufficiently well for practical use by the energy expended in one second by an international ampere in an international ohm.

*Power.* The Watt is equal to  $10^7$  units of power in the c.g.s. system, and is represented sufficiently well for practical use by the work done at the rate of one Joule per second.

*Inductance.* The Henry is the induction in a circuit when an electromotive force induced in this circuit is one international volt, while the inducing current varies at the rate of one ampere per second.

## CHAPTER IX.

### ELECTROMAGNETIC WAVES.

The electromagnetic medium. The propagation of an electromagnetic disturbance. The ratio of the electrostatic and the electromagnetic units. The relation between dielectric constants and optical refractive indices. The experiments of Hertz. Wireless telegraphy. The origin and mode of propagation of waves of light. The energy of the electromagnetic field. The momentum in the electromagnetic field. Magnetic forces as due to the motion of electrostatic tubes of force.

**66.** FARADAY was the first to fix his attention on the dielectric medium as the essential seat of electrical processes.

The electro-  
magnetic  
medium.

As we saw in Chapter III., it was to Faraday's "obstinate disbelief" in action at a distance that we

owe most of his researches. Faraday had no skill in mathematical analysis, and his conceptions were much in advance of the general knowledge of his time. As was said by the great German physicist von Helmholtz in his Faraday Lecture for 1881, "Now that the mathematical interpretation of Faraday's conceptions regarding the nature of electric and magnetic forces has been given by Clerk Maxwell, we see how great a degree of exactness and precision was really hidden behind the words, which, to Faraday's contemporaries, appeared either vague or obscure."

Taking up Faraday's ideas, and developing them in new directions, Maxwell pointed out that, if the energy of an electromagnetic system resided in the dielectric medium, it was probable that the energy passed through that medium with a finite velocity. When, for instance, an alternating current in one circuit is inducing a secondary alternating current in another circuit at a distance,

the energy must pass through the intervening space in some alternating form also. A wave motion of some kind is thus suggested, and a medium is required to carry the waves—to supply what the late Lord Salisbury once called “a nominative case to the verb ‘to undulate.’”

In the chapter of his great book on Electricity and Magnetism, wherein Clerk Maxwell gave to the world his complete theory of electromagnetic waves, he writes:

“In several parts of this treatise an attempt has been made to explain electromagnetic phenomena by means of mechanical action transmitted from one body to another by means of a medium occupying the space between them. The undulatory theory of light also assumes the existence of a medium. We have now to show that the properties of the electromagnetic medium are identical with those of the luminiferous medium.

“To fill all space with a new medium whenever any new phenomenon is to be explained is by no means philosophical, but if the study of two different branches of science has independently suggested the idea of a medium, and if the properties which must be attributed to the medium in order to account for electromagnetic phenomena are of the same kind as those which we attribute to the luminiferous medium in order to account for the phenomena of light, the evidence for the physical existence of the medium will be considerably strengthened.

“But the properties of bodies are capable of quantitative measurement. We therefore obtain the numerical value of some property of the medium, such as the velocity with which a disturbance is propagated through it, which can be calculated from electromagnetic experiments, and also observed directly in the case of light. If it should be found that the velocity of propagation of electromagnetic disturbances is the same as the velocity of light, and this not only in air, but in other transparent media, we shall have strong reasons for believing that light is an electromagnetic phenomenon, and the combination of the optical with the electrical evidence will produce a conviction of the reality of the medium similar to that which we obtain, in the case of other kinds of matter, from the combined evidence of the senses.”

As we shall see, this identity of velocity has been demonstrated

by experiment, and, as Maxwell says, the evidence for the existence of a luminiferous and electromagnetic medium—an æther—is the same in kind, perhaps as strong in degree to those capable of judgment, as the evidence for the existence of other kinds of matter which we can touch and handle. The question whether this evidence is enough to demonstrate the real physical existence of entities corresponding to our conceptions of the æther or a table remains an inquiry for that branch of philosophy known as metaphysics. Natural science demands the conceptions of æther and table to bring order into our mental picture of the universe, but natural science alone is unable to decide whether definite and ultimate realities exist, corresponding to our conceptions. The unity and simplicity which these conceptions introduce into our model of phenomena are valid metaphysical arguments in favour of their ultimate existence, but the arguments are metaphysical arguments, not scientific ones, in the limited sense of that word. Most men of science are realists, but their beliefs on such questions are metaphysical hypotheses or philosophic dogmas, not the definite conclusions of natural science.

**67.** Let us now consider a simple electric system by the properties of which we may investigate the propagation of an electromagnetic disturbance through an isotropic medium. Let *A* and *B* represent two vertical metallic plates, forming a condenser charged with equal and opposite quantities of electricity uniformly distributed over each plate. The dielectric medium between the plates is in a state of strain, and straight horizontal Faraday's tubes of force may be supposed to run from the one plate to the other.

If the top of the plates be connected by means of a wire of high resistance, the plates are discharged. There is a flow of positive electricity up one plate, and of negative electricity up the other. Corresponding with this process, the electric tubes of force move vertically upwards towards the wire, in which they contract and disappear, as described on page 58.

While the tubes are moving upwards between the plates, let

The propaga-  
tion of an  
electro-  
magnetic  
disturbance.

Fig. 91.

their velocity be  $v$ . One tube of force is supposed to proceed from each unit charge, so that the number of tubes per unit area of each plate is equal to  $\sigma$ , the surface density of electrification over it.

Now let us consider the magnetic force due to the two current-sheets which pass up one plate and down the other. By an investigation similar to that adopted in the case of the solenoid on page 100, it follows that the magnetic force is  $4\pi c_1$ , where  $c_1$  is the current across unit length normal to the line of flow. The magnetic force, it will be seen, acts in a direction normal to lines of current-flow and normal to the electric tubes of force,—that is, in a direction perpendicular to the plane of the paper in the figure.

But the current across unit length is measured by the product of the charge per unit area into the velocity with which the charge moves. Thus  $c_1$  may be replaced by  $\sigma v$ , and the magnetic force between the plates is  $4\pi\sigma v$ .

As shown on page 55, the dielectric polarization  $P$  in the dielectric medium, is measured by  $fk/4\pi$ , where  $f$  is the electric intensity, and  $k$  the dielectric constant. This quantity  $fk/4\pi$  is also equal to  $\sigma$ , the surface density on the plates, and therefore to the number of Faraday's tubes per unit cross area. We thus have, for the magnetic force,

$$H = 4\pi P v,$$

and, for the magnetic induction,

$$B = 4\pi P v \mu.$$

Now the essence of Maxwell's theory consists in the recognition of the magnetic effects of dielectric currents: that is, the recognition that a magnetic force is produced by a change in the dielectric polarization, a change which is equivalent to a motion of Faraday's tubes of electrostatic force. Let us, then, dismiss all ideas of conductors, and of ordinary electric currents in them, and fix our attention on a region of the dielectric medium through which are passing a succession of Faraday's tubes. According to the theory of Faraday and Maxwell, the existence of a magnetic force means the motion of electric tubes, and the magnetic force is  $4\pi$  times the product of the number of tubes per unit cross area, a number which gives us  $P$  in the above equation, and of the velocity of the

tubes at right angles to their length. The direction of the magnetic force is at right angles both to the length of the electric tubes, and to the direction of their motion.

Let us now return to the consideration of the propagation of a disturbance through the electromagnetic field, and approach the question from another side. Let us imagine that part of a circuit consisting of a long straight current is moved in a magnetic field at right angles to its length and at right angles also to the direction of magnetic induction  $B$ . The rate of change of induction through the circuit is  $Blv'$ , where  $l$  is the length of the moving wire, and  $v'$  its velocity. Hence the electromotive force in the wire, or the difference of potential set up between its ends, is  $Blv'$ . Exactly the same effect is produced if we suppose the wire to be at rest, and the magnetic induction to be propagated through the field with the same velocity  $v'$ .

Once more let us suppose that we eliminate from our minds the idea of a conductor, and imagine the equivalent processes to occur in the field alone. The current is replaced by a change in the dielectric polarization, that is, by a movement of the electric tubes of force. Along the length  $l$  of the line of the motion there exists an electromotive force  $E$ , and thus at each point there is an electric intensity

$$f = \frac{E}{l} = Bv'.$$

But we have shown already that the motion of the electric tubes of force sets up a magnetic induction at right angles both to their length and to their direction of motion, and that

$$B = 4\pi P v \mu.$$

Thus, in the direction of motion of the electric tubes, a wave of magnetic induction is propagated with the same velocity. This represents an electromagnetic disturbance, and, putting  $v$  equal to  $v_1$ , we obtain a second relation between the quantities from the equation

$$f = Bv.$$

On page 37 it was shown that the electric intensity between two charged planes was given by the relation

$$f = \frac{4\pi\sigma}{k}.$$

Hence, since the surface density of electrification  $\sigma$  is numerically equal to  $P$  the dielectric polarization, we have

$$f = \frac{4\pi P}{k},$$

a result which is true from point to point in the medium, and therefore is independent of the particular system considered in establishing it.

We now have two equations for  $B$ ,

$$B = 4\pi P v \mu$$

and

$$B = \frac{f}{v} = \frac{4\pi P}{vk}.$$

Therefore,

$$4\pi P v \mu = \frac{4\pi P}{vk},$$

or

$$v^2 = \frac{1}{k\mu},$$

and

$$v = \frac{1}{\sqrt{k\mu}},$$

and this result, on Maxwell's theory, gives the velocity of an electromagnetic disturbance propagated through an isotropic medium possessing a dielectric constant  $k$  and a magnetic permeability  $\mu$ .

**68.** In the last chapter on electrical units we saw that the dimensions of the electrostatic units, as ordinarily defined, were different from those of the usual electromagnetic units for corresponding quantities. We also found that the ratio of any pair of units involved a velocity or some power of a velocity, and that the

The ratio of the electrostatic and the electromagnetic units.

velocity in question was measured by  $1/\sqrt{k\mu}$ . Thus it follows that, by comparing the numerical values of some one pair of units, we may determine the velocity with which an electromagnetic disturbance is propagated through the medium.

Much experimental skill has been devoted to the measurement of the number of electrostatic units in one electromagnetic unit of some electrical quantity. Weber and Kohlrausch found that one electromagnetic unit of quantity of electricity contained

$3.1074 \times 10^{10}$  electrostatic units. Lord Kelvin compared the two units of potential, and found a value for  $v$  of  $2.93 \times 10^{10}$  centimetres per second. Clerk Maxwell balanced a force of electrostatic attraction against one of electromagnetic repulsion, and obtained  $2.88 \times 10^{10}$ .

On the whole, however, the most convenient pair of units to deal with are those of capacity; and experiments have been made by Ayrton and Perry, J. J. Thomson and Searle, and others, by this method. The electrostatic capacity of a condenser of regular form may, as we have seen, be calculated in simple cases from a knowledge of its form and dimensions. The same quantity, or the capacity of another condenser which may be compared with the first one, may be determined in electromagnetic measure in one of several ways. The most obvious method consists in charging the condenser to some known potential-difference by means of a standard voltaic cell, and then discharging it through a ballistic galvanometer, of which the constant is also determined. By this method Ayrton and Perry estimated  $v$  to be  $2.980 \times 10^{10}$  centimetres per second. Another arrangement, suggested by Maxwell and used by J. J. Thomson and Searle, consists in placing a condenser in one arm of a Wheatstone's bridge, and continually charging and recharging it by means of a vibrating tuning fork (Fig. 92).

A series of electric charges is thus conveyed through the arm of the bridge, and, if the period of the fork is very rapid compared with the swing of the needle of the galvanometer, the discontinuous electric transfer through the con-

Fig. 92.

denser-arm is equivalent to a continuous current. The charge conveyed by each vibration of the fork is  $CV$ , where  $C$  is the capacity of the condenser, and  $V$  the difference of potential between its plates. If  $n$  be the number of complete vibrations of the fork, or the number of charges per second, the effective current is  $nCV$ . Now a steady current would be given by  $V/R$ , where  $R$  is the resistance. Hence, the effective resistance of the arm of the bridge in which the condenser is inserted is  $1/nC$ .

From such considerations it is possible to calculate the capacity of the condenser by applying Kirchhoff's laws to the bridge. Thomson and Searle compared the capacity of the bridge-condenser with that of two concentric cylinders. By calculating the latter quantity in electrostatic units, they found that  $v$  was  $2.9958 \times 10^{10}$  centimetres per second.

The mean of the determinations of the quantity  $v$  is thus very near the value  $3 \times 10^{10}$  centimetres per second. Now, within the narrow limits of experimental error, the observed velocity of light is also  $3 \times 10^{10}$  centimetres per second. In Maxwell's words, "we have strong reasons for believing that light is an electromagnetic phenomenon."

69. Another consequence of the theory may be submitted to experimental examination. The velocity of an electromagnetic wave through air should bear to its velocity through some other transparent medium the ratio  $1 : 1/\sqrt{k\mu}$  or  $\sqrt{k\mu} : 1$ . The magnetic permeability of ordinary transparent media is sensibly equal to that of air, and this ratio becomes  $\sqrt{k} : 1$ . But the ratio of the velocity of light in air to its velocity in another medium measures, on the undulatory theory and in practice, the refractive index  $r$  of that medium. We should look, then, for a connexion between the optical index of refraction and the dielectric constant of different transparent substances; the theory indicates that the refractive index should be equal to the square root of the specific inductive capacity.

The specific inductive capacities tabulated on page 29 are obtained by measuring the relative capacities of condensers when their charges are retained for some considerable time—a time, at all events, comparable with a second. But the refractive index depends on the properties of the medium with respect to the exceedingly rapid vibrations of light, the periods of which are of the order  $2 \times 10^{-15}$  seconds. The quantities are not strictly comparable. An attempt to secure comparable results has been made by determining the refractive indices for a series of vibration frequencies, and estimating their values for a frequency corresponding with an infinite wave length, by some such equation as

that of Cauchy. But there is some doubt as to the accuracy of the values so obtained. Cauchy's formula does not contemplate any anomalous dispersion, and Maxwell's equations take no account of dispersion at all. Any comparison by such methods of the dielectric constants and the refractive indices still remains unsatisfactory.

Substance	$\sqrt{k}$	$r$
Paraffin	1.51	1.42
Benzene	1.54	1.50
Carbon bisulphide	1.63	1.64
Flint glass	3.18	1.71
Quartz	2.13	1.55
Distilled water	8.72	1.33

Thus, with certain substances, great discrepancies exist, though the considerations we have advanced above more than explain any such want of concordance. We are unable to produce electric alternations of periods comparable with those of light, but the electrical vibrations of systems of small capacity have frequencies rising to some hundreds of millions per second, and use has been made of these vibrations to determine some dielectric constants.

As we have seen, electromagnetic disturbances travel with a velocity which, in non-magnetic media, varies inversely as the square root of the dielectric constant. By observing the interference between two parts of an electromagnetic wave which have passed over paths of equal length in air and some other medium respectively, comparisons of velocity have been made. M. Blondlot and Prof. J. J. Thomson independently found that, in rapidly changing fields, the specific inductive capacity of glass was less than in steady fields, and had a value of about 2.8. This gives  $\sqrt{k}$  a value of 1.7, in agreement with the optical measurements of refractive index.

70. Clerk Maxwell published his electromagnetic theory of light in the year 1865. For twenty years the direct evidence in its favour was almost confined to the considerations we have given—the concordance of the value of the velocity involved in the ratio of the electrical

The  
experiments  
of Hertz.

units with the observed speed of light, and the agreement, more or less exact, between the indices of refraction of transparent media and the square roots of their dielectric constants. Maxwell's theory, although generally accepted in England, was but imperfectly known on the Continent, and its merits as a successful means of representing and co-ordinating electrical phenomena were hardly realized.

In 1888, the physical world was startled by the announcement that electromagnetic waves had been produced, and their passage through space demonstrated, by Professor Heinrich Hertz, then of the Karlsruhe Polytechnic, who had found moreover that the waves moved with a speed which, at all events, did not differ much from the velocity demanded by Maxwell's theory—the velocity of light.

In the chapter on electromagnetic induction, it was shown that, on the analogy between self-induction and inertia, the discharge of an electrified system of capacity  $C$  through a circuit of small resistance and of self-induction  $L$ , gave rise to electrical oscillations with a period of  $2\pi\sqrt{LC}$ .

One form of electric oscillator used by Hertz consisted of two metallic plates in the shape of squares with sides 40 centimetres in length. The plates were connected by rods about 30 centimetres long with two small highly polished gilt balls placed 2 or 3 centimetres apart. The plates were connected with the opposite

Fig. 93.

terminals of the secondary circuit of an induction coil. Each time the plates became charged to a certain difference of potential a spark is produced, and electric oscillations are set up. With the apparatus used by Hertz, the period of alternation was about  $1.85 \times 10^{-8}$  seconds. The resistance is high and the self-induction low; consequently very few oscillations occur at each discharge, the energy being partly radiated as waves, and partly dissipated as heat in the spark.

To detect the presence of the electromagnetic waves in the space surrounding the oscillator, Hertz made use of the principle of resonance. When any physical system, possessing a natural period of vibration of its own, is subjected to periodic impulses

which coincide with the natural period of the system, violent oscillations are set up. This principle is illustrated by the timing of the impulses given to a child's swing, and by the sounding of a piano wire of one particular frequency of vibration when a note in unison with its own is sung near it.

Hertz's resonator was formed of a circle of wire about 35 centimetres in radius, separated at one part of its circumference by a spark gap made of two small knobs. By means of a screw, working in an ebonite frame, the knobs could be adjusted at any small distance from each other. We may regard an uncharged conductor as possessing equal charges of the opposite kinds of electricity; and, when properly timed impulses fall on it, electric surgings of these charges will be set up. As the positive charge swings one way and the negative the other, the knobs become oppositely electrified, and their potential-difference may become so great, owing to the kinetic energy of the oscillating charges, that a spark passes.

Fig. 94.

A circle of this size possesses a natural period of electric oscillation about equal to that of the oscillator used by Hertz, and thus, if it be moved about in front of the spark-gap of the oscillator, resonance effects may be observed by the presence of minute sparks, the length of which depend on the position of the plane of the resonator and on the position of the air gap therein.

The electric waves given by Hertz's apparatus may be reflected by metal surfaces, focussed by parabolic mirrors of sheet zinc, and refracted by large prisms of pitch. A frame of parallel wires is transparent to the waves when the wires are perpendicular to the line of the spark, and opaque when the wires are parallel to the spark. In all these respects, the electromagnetic waves show the properties of plane polarized light, in which, according to the undulatory theory, the vibrations occur in straight lines in a plane at right angles to the direction of propagation.

When the waves of the sea impinge directly on a straight wall, they are reflected. Interference results between the direct and reflected waves, and a system of what are called stationary undulations is set up. The motion of the water in front of the wall is

such that no waves appear to be moving forward; any point on the water simply rises and falls periodically. At certain intervals this motion ceases, and we get points called nodes, where the water is stationary. Another illustration of the same principle is given by the transverse vibrations of a stretched string or wire. If both ends be fixed, the fundamental mode of vibration gives a node at each end, and an internode or loop at the middle. This arrangement may be considered to be due to the successive reflection of the waves at the ends of the string. If the string be held lightly at the centre, it may be made to vibrate in halves, and, if it is emitting a sound, the note will be the octave of the first. Other modes of vibration, giving higher overtones, may also be produced, the string being more subdivided. The analogy between the vibrations of the string and the electric waves we have now to consider is best seen if we imagine the vibrations of the string to

Fig. 95.

be set up by connecting one end to a tuning fork, the vibrations of which are maintained electrically, and keeping the other end of the string fixed. Waves pass out from the fork, and, if the length of the string is an exact multiple of the half wave-length of the undulations travelling along it, stationary waves are seen, owing to the persistence of visual impressions, the string being visibly divided into a series of nodes and loops. This system again may be regarded as due to the interference of the direct and reflected trains of waves, and from the figure it will be evident that the distance between two nodes is equal to half the complete wave-length of the undulations travelling along the string. We may point out that, if we know the number of waves per second emitted by the source, and the length of each wave, the product of these two quantities gives us the distance from the source reached

by the first wave in one second—that is, the velocity of the disturbance.

In front of an oscillator such as that described above, Hertz placed a large sheet of zinc to act as a reflector, and set up a system of stationary electric undulations. When he explored the space between the oscillator and the reflector, he found that, at certain places, the length of the sparks obtained in his resonator was a maximum, while, at other intermediate places, the spark-length was a minimum. Thus we obtain by direct experiment the wave-length of electric oscillations of known period, and can deduce an approximate value for the velocity. Within the limits of experimental error, it proves to be the same as that of light. Maxwell's theory receives a direct confirmation, of the most striking kind.

Hertz used a resonator constructed to have as nearly as possible the same period of vibration as the oscillator, and the wave-lengths, as measured by him, are those of the undulations which synchronize both with the vibrations of the oscillator and of the resonator. In repeating his experiments with a series of resonators, Sarasin and de la Rive found that the wave-length indicated by the distance between the successive nodes was the wave-length of the vibrations of the resonator, not of the oscillator. The explanation of this result is found in the fact that a system like the oscillator is a very good radiator of electromagnetic energy, and soon loses its amplitude of oscillation. The amplitude of the tenth swing has been shown to be only about the  $1/14$  of the first. On the other hand, the resonator has been shown to be a very slow radiator; oscillations once set up in it maintain their energy for a considerable time, and more than a thousand swings are needed to reduce the amplitude to  $1/10$  of its original value. When the disturbance from the oscillator falls on the resonator, electric surgings are set up, even though the tuning be incomplete; the first few impulses being almost the only effective ones. The resonator goes on vibrating long after the train of waves from the oscillator has ceased; and, although its energy of radiation is much less, it is the direct and reflected waves from the resonator which form the persistent stationary wave-system investigated in the region in front of the reflector in the experiments of Hertz and in those of Sarasin and de la Rive.

We have seen that the energy of an electric current passes through the dielectric medium, the current in a wire being merely the line of dissipation of the energy into heat. But, just as a wire serves to direct the flow of energy in a steady current, so the energy of electromagnetic waves may be guided along wires. Here again, the waves pass through the surrounding medium, and must travel with the velocity of light in air, and with the velocity  $1/\sqrt{\mu k}$  through other substances. While in the field surrounding a long straight steady current, Faraday's tubes will be parallel to the current, and will be moving into the wire at right angles to their length, with rapidly alternating disturbances, the electric tubes will be radial to the wire and will move backwards and forwards along the wire with one end slipping along in its substance.

**71.** The theory of Clerk Maxwell and the experiments of Hertz have borne practical fruit in their application to the problems of telegraphy. The resonator used by Hertz is not a convenient means of detecting the incidence of electromagnetic waves passing through free space, and better arrangements were necessary before technical use could be made of the new discoveries.

Sir Oliver Lodge, adapting an observation of M. Branly, introduced a form of detector known as the coherer. If a glass tube have two platinum wires sealed into its ends, and be filled with metallic filings, the electrical resistance between the wires is, in the normal state of the tube, very great. If, however, electromagnetic radiation is falling on the tube, the resistance is much diminished, and a current will pass through a relay circuit including a battery, a galvanometer, and the coherer. If the coherer be kept constantly tapped, so as to shake the filings, it returns to its initial state of high resistance when the waves cease, and the current through it is stopped.

Receivers of still more recent date are founded on the effect of electromagnetic waves in demagnetizing iron. If a piece of iron be rotated in a magnetic field, its magnetization lags behind the magnetizing force owing to hysteresis. Thus, a compass-needle may be deflected through an angle which depends on the hysteresis of

the iron. When electromagnetic waves arrive, the iron follows the magnetizing force more closely, the hysteresis effect is diminished, and the deflection of the needle changed. Instruments of this type have been used by Marconi and by Ewing and Walter.

Another type of receiver has been described by Lodge and Muirhead. It depends on the effect of electromagnetic radiation on the resistance between a small revolving metallic wheel and a quantity of mercury covered with a film of oil; the rim of the wheel dips into the mercury.

For long-distance signalling, large quantities of energy are necessary, and as much of that energy as possible must be collected at the receiving station. Hence it was only when Marconi introduced the use of an insulated vertical wire 100 or 150 feet in height to collect the radiation, that it became possible to telegraph over great distances. The arrangement of a simple form of apparatus for wireless telegraphy is shown in Figure 96. The induction coil

Fig. 96.

*I* is connected with a spark-gap *S*, the opposite sides of which are joined, one to the earth, and the other to the long aerial wire *A*.

At the receiving station, another aerial wire is connected with one terminal of the coherer, the other being put to earth. The coherer is also in a relay circuit, consisting of a battery, a bell, and two coils  $LL'$  possessing self-induction.

In more recent forms of apparatus the oscillations are induced in the aerial wire of the transmitting station by other oscillations in a primary circuit of larger capacity and energy-storing power. This plan increases greatly the effective range. The receiving station is also furnished with two circuits, and oscillations are induced in the coherer circuit by those set up in the sky-wire. By adjusting the periods of vibration of the four circuits, it has been found possible to prevent, to some extent, the responding of the receiver to other oscillations than those intended.

**72.** It is interesting to consider how a wave of light must start and be propagated through the æther. If light is an electromagnetic wave, it must have an electrical origin. And, indeed, as we shall see in a future chapter, cumulative evidence of overwhelming strength indicates that the atoms of bodies, from the vibrations of which light must arise, are composed of aggregations of corpuscles each associated with, or identical with, a negative electric charge.

Now let us consider, in a manner suggested by Prof. J. J. Thomson, an isolated charged body, shown in figure 97.

The lines of electric force must evidently be radial, as shown in the region near the particle  $O$ , where  $Op$  represents one such line of force proceeding from the electric charge at  $O$ . If the electrified particle be travelling forwards, in the direction of the arrow, it carries its lines of force with it; and, unless the particle be moving with a velocity very nearly equal to the velocity of light, the distribution of the lines is unaltered; they still are uniformly spaced radii, proceeding

Fig. 97.

from the particle as centre. Whenever electric tubes of force are moving, there exists a magnetic force at right angles, both to their length and to their direction of motion, and therefore a magnetic field must be produced by the moving particle  $O$ .

Now let us imagine the moving particle to be stopped suddenly. If a change could be propagated instantaneously throughout all space, the lines of force would stop at once also. But a change in electromagnetic properties can be propagated only with the speed of an electromagnetic wave, that is, with the velocity of light. Thus, when a moving electrified particle is arrested, a pulse of electromagnetic force starts from the particle as its centre, and spreads out in circles, rectifying the distribution of the lines of force as it goes. The effect is shown in Fig. 97. If the particle had not been stopped, at the end of an interval of time,  $t$ , it would have reached some new position  $O'$ , and the lines of force would be radii from this point as centre. Beyond the sphere reached by the rectifying pulse, the lines of force will still be moving parallel to the direction of motion of  $O$ , and, at the instant considered, will be radii of the point  $O'$ , while, behind the spherical pulse, the lines will be at rest, and will be radii of the point at which the particle is stopped. The lines of force must be continuous; and therefore, in the pulse itself, the lines must run in some direction such as  $pq$  in the figure. The electric force near  $pq$  has then a component at right angles to the direction of propagation of the disturbance, that is, at right angles to the radial lines. Whenever a Faraday tube of electric force moves, it produces a magnetic force at right angles both to its length and to its direction of motion, and thus the line of force  $pq$  within the pulse produces a magnetic force at right angles to the plane of the paper. Now the waves of light, and, to pass to much greater wave-lengths, the waves used in wireless telegraphy, are æthereal waves of electromagnetic force so arranged that the electric and magnetic forces are at right angles to each other, and both at right angles to the direction of propagation of the waves. It follows that the pulse, indicated by our figure as spreading out, consequent on its arrest, from a moving electrified particle, is a pulse of the same nature as the waves of light, with this exception, that, instead of a series of regular periodic waves, it consists of a single expanding shell of electromagnetic force.

But, if, instead of imagining the moving corpuscle suddenly brought to rest, we suppose that it is reversed in its path, and that this reversal occurs periodically, so that the corpuscle performs simple harmonic vibrations, we get, instead of a single thin pulse, a series of less abrupt but regularly recurring alternations propagated out from the corpuscle as centre. Each Faraday's tube is set into oscillation at its inner end, and transverse waves travel outwards along it, just as waves travel along a stretched cord, when one end is oscillated periodically by the hand. The distribution of electric and magnetic force in the advancing wave-front is exactly the same as in the case of the sudden pulse already studied: we get, in fact, a series of regular æthereal waves, in which there are electric and magnetic forces, both in the plane of the wave-front and at right angles to each other in that plane. But such an arrangement is precisely that required to explain the phenomena of light.

In the simple case we have taken, the corpuscle oscillates backwards and forwards in a straight path: the vibrations travel as tremors along the tubes of force in one plane only; the resultant light is plane polarised. In the more general case, we must suppose that the corpuscle oscillates in a circular, or elliptical orbit, and the tubes of force will be displaced in corresponding motions; the tremors running along them will no longer be simple to and fro movements; points on the tubes will describe curved paths. These paths change continually as the orbit of the corpuscle changes, and we get a complete model of the propagation of common, non-polarised light.

Faraday's tubes, it is clear, give a very powerful and convenient method of studying the phenomena of the electromagnetic field, and indications are not wanting that they represent something more than a useful mathematical fiction. If the structure of the electric field be discontinuous in reality, as our tube-picture of it indicates; if the electric and magnetic effects of a charge of electricity are in reality exerted throughout the surrounding space by means of discrete tubes of force—vortex filaments in the æther, or whatever they may actually be—an advancing wave of light must be discontinuous also. Could we look at such a wave from the front, and magnify it millions of millions of times, we should see, not a uniform field of illumination, but a number of bright

specks scattered over a dark ground. Each tube of force would convey its own tremors, and these would constitute light, but between them would lie undisturbed seas of æther.

Such an idea about the nature of a wave-front of light is very unexpected and surprising. We are inclined at once to relegate our tubes of force to a museum of conceptual curiosities. But it is a remarkable thing that certain evidence in favour of the discontinuous nature of a wave-front of light really does exist. This evidence depends on electric conduction through gases, the phenomena of which will be described in a future chapter.

**73.** The laws of force are, as we have seen, of the same form

The energy of  
the electro-  
magnetic  
field.

for magnetism as for electrostatics, when pole-strength replaces charge, and magnetic permeability is put instead of specific inductive capacity. The energy of

the electrostatic field (§ 23) is  $f^2 k / 8\pi$  per unit volume, where  $f$  denotes the electric intensity; and it must follow, by a similar method of proof, that the energy per unit volume of a magnetic field is  $H^2 \mu / 8\pi$ , where  $H$  is the magnetic force.

Now, in terms of Faraday's tubes of electric force, we explain a magnetic force as due to the motion of the electric tubes at right angles to their length, and thus, if the tubes move with a velocity  $v$ , we have, as in § 67,

$$H = 4\pi Nv,$$

when the number of tubes per unit cross area is  $N$ , and the tubes move at right angles to their length. If the direction of their motion makes an angle  $\theta$  with their length,

$$H = 4\pi Nv \sin \theta.$$

We may now write the magnetic energy per unit volume of the field in terms of the number and velocity of Faraday's tubes of electrostatic induction. The magnetic energy has the value

$$\begin{aligned} \frac{H^2 \mu}{8\pi} &= \frac{\mu}{8\pi} (4\pi Nv \sin \theta)^2 \\ &= \frac{1}{2} 4\pi \mu N^2 v^2 \sin^2 \theta. \end{aligned}$$

If we regard this energy as the kinetic energy of the tubes, and the expression for the energy as analogous to the familiar

formula  $\frac{1}{2}mv^2$ , we see that the energy is that of a mass  $4\pi\mu N^2$  moving with the velocity of the tubes in a direction at right angles to their length.

The kinetic energy of a freely moving body does not depend on the direction of motion, but a dynamical analogy with the magnetic energy of the tubes is found in the kinetic energy of a cylinder moving through a liquid.

A body travelling through a liquid drags some of the liquid with it, and thus the effective mass of the body is increased. If the body be a sphere, the added mass is evidently independent of the direction of motion; but, if a cylinder be made to travel, it will carry more liquid when going sideways than when proceeding in the direction of its length. If its length be very great compared with its breadth, it will, when moving in the direction of its length, simply glide through the liquid, and, if that liquid possesses no viscosity, none of it will be dragged forwards with the cylinder. Moving sideways the cylinder will be accompanied by a certain mass  $M$  of the liquid, and moving at an angle  $\theta$  with its length, it will have momentum  $Mv \sin \theta$  at right angles to its length, the energy due to the liquid in motion being  $\frac{1}{2}Mv^2 \sin^2 \theta$ .

Our analogy is now clear. The magnetic energy of the field is  $\frac{1}{2} 4\pi\mu N^2 v^2 \sin^2 \theta$ ; and thus we may say that the energy is the same as the kinetic energy which would exist if real tubes moved through a material frictionless liquid, and carried with them a mass of that liquid, the total mass being equal to  $4\pi\mu N^2$  when the tubes moved at right angles to their length. We may imagine, in fact, that Faraday's tubes are portions of the æther differentiated from the rest, perhaps by vortex motion, and that these vortex filaments carry with them a total mass of æther equal to  $4\pi\mu N^2$ .

The mass of æther bound to each tube is  $4\pi\mu N$ , and therefore depends on the number of tubes per unit cross area. This result increases the completeness of the analogy with a moving cylinder, for a system of many cylinders fixed together would drag forward more liquid than would the same number of cylinders if moving independently.

The electrostatic potential energy per unit volume of the field is  $f^2 k / 8\pi$ , and, as we saw in § 22, the number  $N$  of Faraday's tubes

per unit area, which measures the electrostatic polarization, is  $fk/4\pi$ . Hence the potential energy per unit volume is  $fN/2$ , or, since  $f$  is  $4\pi N/k$ , the energy is  $2\pi N^2/k$ .

The bound mass  $M$  of æther is  $4\pi\mu N^2$ , and therefore the potential energy per unit volume is

$$\frac{1}{2}M \frac{1}{\mu k} = \frac{1}{2}MV^2,$$

where  $V$  is the velocity of light in the medium. Hence the electrostatic potential energy of the field is equal to the kinetic energy which the bound mass would possess if moving with the velocity of light.

The energy of a charged condenser is the potential energy of electrostatics. When the condenser is discharged by means of a wire, the statical energy changes suddenly into the kinetic energy of moving Faraday's tubes, and, in the end, this energy is converted into heat in the conducting wire. Meanwhile, oscillation may be set up, alternations of potential and kinetic energy occur, and electromagnetic waves be emitted.

In wave motion, we are accustomed to look for changes in energy from the kinetic to the potential form; hence, on our present analogy, we should regard the energy of an electromagnetic wave as alternating from the magnetic to the electric form. When all the energy is kinetic, its value per unit volume is  $H^2\mu/8\pi$ , and when potential,  $f^2k/8\pi$ .

**74.** If we refer the energy of the magnetic field to the kinetic energy of moving tubes of electric force, it follows that the field must contain momentum—the momentum, in fact, of the tubes and the bound æther which we may imagine to be dragged along with them.

The energy of the magnetic field is  $\frac{1}{2}4\pi\mu N^2v^2\sin^2\theta$ , with the same notation as above, and the effective mass  $M$  of the tube and its attendant æther is  $4\pi\mu N^2$ . The momentum  $Mv$  is thus  $4\pi\mu N^2v\sin\theta$ , or, if we take the simplest case, when the tubes move at right angles to their length,  $4\pi\mu N^2v$ . Since the magnetic force  $H$  is  $4\pi Nv$ , we may write this momentum as  $\mu HN$  or  $BP$ , where  $B$  is the magnetic induction and  $P$  the electrostatic polarization of the medium.

Now it is important to understand that this æthereal momentum has an existence quite as real as the momentum of an ordinary moving body. Momentum can pass freely from æther to matter, and from matter back again to æther. If this were not so, we could not extend Newton's laws of motion to a system consisting of a charged body and a medium through which passes an electric pulse. The body would be set in motion, and, unless we take into account the momentum in the medium, action and reaction would not be equal and opposite.

Another important case is that of an electromagnetic wave falling normally on an absorbing surface. Here we have energy alternating between the kinetic and potential forms, and, in any given volume of the medium, we may take half the energy at any instant to be the kinetic energy of moving tubes. The energy per unit volume of the medium is  $\frac{1}{2}4\pi\mu N^2v^2$ , and, on the average, half of this is kinetic. The average momentum, then, is half that corresponding with steady motion, or  $\frac{1}{2}4\pi\mu N^2v$  per unit volume.

The radiation in  $v$  units of volume of the medium reaches unit area of the receiving surface in one second. Hence, the momentum communicated to unit area of the surface per second, that is, the pressure on the surface, is  $\frac{1}{2}4\pi\mu N^2v^2$  which, it will be noted, is equal to the total energy, kinetic and potential, contained in unit volume of the medium.

We have supposed the surface to absorb the radiation. If we use a reflector, the momentum is returned to the medium in the reverse direction, so that the change of momentum is doubled, and the pressure of radiation is doubled with it.

A body exposed to electromagnetic radiation of any kind, including light, will be pushed in the direction of the incident beam by a pressure which is calculable if we know the amount of energy received per second and the velocity of light. For instance, the heat received per square centimetre by surfaces exposed normally to bright sunlight on the earth is about 2 thermal (gramme-degree-centigrade) units per minute, or  $1/30$  heat unit per second. In dynamical units of energy, this is equal to  $4.2 \times 10^7/30$ , or  $1.4 \times 10^6$  ergs per second. This quantity of energy, received on one square centimetre in one second, is, at the beginning of the second, spread out through space, occupying a

column one square centimetre in cross section, and 186,000 miles, or  $3 \times 10^{10}$  centimetres, in length. The energy per unit volume, then, is, at any instant,

$$\frac{1.4 \times 10^6}{3 \times 10^{10}} = 4.7 \times 10^{-5} \text{ ergs per cubic cm.}$$

This number must also represent the force per unit area, in dynes per square centimetre. Hence, on one square metre of an absorbing surface, exposed to bright sunlight, the force is

$$0.47 \text{ dyne} = 0.46 \text{ milligram-weight.}$$

This pressure, which we have calculated from the conception of the momentum of moving tubes of force, was originally deduced by Maxwell as a consequence of the electromagnetic theory. Larmor has shown that it is necessary on any theory of undulations, and Bartoli has deduced it on thermo-dynamical principles by an application of Carnot's idea of the reversible cycles of a heat engine.

As we have seen, on a reflecting surface the pressure is twice as great as on an absorbing surface, and, by seeking for the difference between the forces on the absorbing and reflecting surfaces of light suspended vanes, Professor Lebedef of Moscow has demonstrated experimentally the existence of this minute radiation-pressure, and his results have been confirmed and extended by Professors Nichols and Hull in America.

### 75. An electrostatic charge is the origin of Faraday's tubes of

forces as due  
to the motion  
of electro-  
static tubes of  
force.

electric force, and thus, on Maxwell's theory, the motion of a charged conductor should produce a magnetic field like that due to a current.

This conclusion has been confirmed experimentally by Rowland, Pender, and others. Two circular plates, divided into sectors by insulating divisions, are fixed parallel to each other, on one axis, which passes through their centres and is normal to their planes. When the sectors are similarly electrified and set in rotation, a magnetic force is produced, equivalent to that which would be caused by circular currents flowing in the direction of motion of the electric charges. The magnetic field can be detected by the deflection of a needle suspended between the plates.

A permanent steel magnet is accompanied by a steady magnetic field in its neighbourhood. On our present theory, that field must be due to the motion of Faraday's tubes of electrostatic force, and hence the magnet must be the centre of a whirlpool of electric tubes. The work done in magnetizing a steel bar must include the energy needed to set this whirlpool in motion, and, once established, the whirlpool must be regarded as inseparable from the magnet itself. If we move the magnet, we move with it its attendant system of rotating electric tubes.

In a steady magnetic field there are no electromotive forces—no induced currents are found unless the magnetic field is changing. But a single tube of electrostatic force implies an electric intensity, which tends to move electricity, and thus to set up a current. We are driven to conclude, therefore, that, in a steady magnetic field, negative as well as positive tubes of electric force must exist in motion, and that as many negative as positive tubes enter any element of volume per second.

Another aspect of this problem is seen if we remember that positive electric charge induces negative charge on a metal plate in its neighbourhood. If the positive charge be set in motion, it produces a magnetic force, which acts through the metal plate unless that plate be made of thick iron. On the usual view of electrostatic tubes of force, we should imagine them as springing from the positive charge, and ending on the induced negative charge, and it is difficult to see how their motion could then cause a magnetic field beyond the metal screen. For reasons such as these, Professor J. J. Thomson now conceives the electrostatic tubes of force to start from both positive and negative units of charge, and to run from these charges out into space. If we imagine, as above, that the nature of the electric tubes may be represented mentally by some such idea as that of vortex filaments in the æther, it is easy to picture positive and negative tubes as oppositely circulating vortices.

These tubes will attract each other if of opposite kind, and will repel each other, as Faraday supposed, if of the same kind. As far as electrostatic action is concerned, Thomson's new conception is equivalent to the older ideas, but it has the advantage of being applicable also to electrodynamic phenomena. The exact meaning

of positive and negative electricity remains, however, uncertain. In a future chapter, we shall return to the question of the relation between them.

Whether Faraday's tubes of force are ultimate realities remains, like all similar questions, a problem of metaphysics. But, if we hold the realist creed at all, it is difficult to deny a physical basis to ideas which enable us to explain and co-ordinate so many and different sense-perceptions.

If we grant them provisionally a real existence, the nature of the tubes remains to be investigated. The idea of vortex filaments in the æther, which we have used above to give definiteness to our conceptions, may possibly represent some true relation; at present it is no more than a useful working hypothesis.

## CHAPTER X.

### ELECTROLYSIS.

Early History. Polarization. The nature of the ions. Faraday's Laws. Electrochemical equivalents. The conductivity of electrolytes. Experimental methods. Experimental results. The migration of the ions and transport numbers. Mobility of the ions. Experimental measurements of ionic velocity. Voltaic cells. Reversible cells. Concentration cells. Chemical cells. Secondary cells or accumulators. Volta's contact effect. Single potential differences at the junctions of metals with electrolytes. Electric endosmose. The theory of electrolytic dissociation. Osmotic pressure. Chemical relations. The electrical properties of colloidal solutions.

**76.** IN Chapter V. on the Electric Current, we described the origin of the voltaic cell and the change it effected in the direction of the main stream of electrical research. The attention of physicists, who had been occupied with the phenomena of electrostatics and of the disruptive discharge of electric machines and Leyden jars, was turned to the new field of inquiry, and the opening years of the nineteenth century witnessed a rapid development of knowledge, particularly in the chemical effects of the so-called galvanic or voltaic currents.

The fundamental observation, from which arose the science of electro-chemistry, was made in the year 1800, immediately on the news of Volta's discovery reaching England.

Using a copy of Volta's original pile, Nicholson and Carlisle found that when two brass wires leading from its terminals were immersed near each other in water, there was an evolution of hydrogen gas from one, while the other became oxidised. If platinum or gold wires were used, no oxidation occurred, but

oxygen was evolved as gas. They noticed that the volume of hydrogen was about double that of oxygen, and, since this is the proportion in which these elements are contained in water, they explained the phenomenon as a decomposition of water. They also noticed that a similar kind of chemical action went on in the pile itself, or in the cups when that arrangement was used.

Soon afterwards, Cruickshank decomposed the chlorides of magnesia, soda and ammonia, and precipitated silver and copper from their solutions—an observation which afterwards led to the process of electroplating. He also found that the liquid round the pole connected with the positive terminal of the pile became alkaline and the liquid round the other pole acid.

In 1806 Sir Humphry Davy proved that the formation of the acid and alkali was due to impurities in the water. He had previously shown that decomposition of water could be effected although the two poles were placed in separate vessels connected together by vegetable or animal substances, and established an intimate connexion between the galvanic effects and the chemical changes going on in the pile.

The identity of “galvanism” and electricity, which had been maintained by Volta, and had formed the subject of many investigations, was established in 1801 by Wollaston, who showed that the same effects were produced by both, while in 1802 Erman measured with an electroscope the potential differences furnished by a voltaic pile.

In 1804 Hisinger and Berzelius stated that neutral salt solutions could be decomposed by electricity, the acid appearing at one pole and the metal at the other, and drew the conclusion that nascent hydrogen was not, as had been supposed, the cause of the separation of metals from their solutions. Many of the metals then known were thus prepared, and in 1807 Davy decomposed potash and soda, which had been considered to be elements, by passing the current from a powerful battery through them when in a moistened condition, and so isolated the metals potassium and sodium.

The decomposition of chemical compounds by electrical means indicated a connexion between chemical and electrical forces. Davy “advanced the hypothesis that chemical and electrical

attractions were produced by the same cause, acting in one case on particles, in the other on masses." This idea was developed by Berzelius, who regarded every compound as formed by the union of two oppositely electrified parts—atoms or groups of atoms. The exact dualistic formulation of his theory given by Berzelius was afterwards abandoned, but the essence of the idea—the explanation of chemical forces in terms of electrical conceptions—remains to this present.

The remarkable fact that the products of decomposition appear only at the poles was perceived by the early experimenters on the subject, who suggested various explanations. Grotthus in 1806 supposed that it was due to successive decompositions and recombinations in the substance of the liquid. Thus, if we have a compound  $AB$  in solution, the molecule next the positive pole is decomposed, the  $B$  atom being set free. The  $A$  atom attacks the next molecule, seizing the  $B$  atom and separating it from its partner, which attacks the next molecule and so on. The last molecule in the chain gives up its  $B$  atom to the  $A$  atom separated from the last molecule but one, and liberates its  $A$  atom at the negative pole.

Fig. 98.

A new terminology, which is still used, was introduced by Faraday in 1833. Instead of the word *pole*, which implied the old idea of attraction and repulsion, he used the word *electrode*, and called the plate of higher electric potential, by which the current is usually said to enter the liquid, the *anode*, and that by which it leaves the liquid, the *cathode*. The parts of the compound which travel in opposite directions through the solution he called *ions*—*cations* if they went towards the cathode, and *anions* if they went towards the anode. He also introduced

the words electrolyte, electrolyse, etc., which we have already used.

Faraday pointed out that the difference between the effects of a frictional electric machine and of a voltaic battery lay in the fact that the machine produced a very great difference of potential, but could only supply a small quantity of electricity, while the battery gave a constant supply, much larger in quantity, but only produced a very small difference of potential.

**77.** If we connect together in series a single Daniell's cell, a galvanometer, and two platinum electrodes dipping  
*Polarization.* into acidulated water, no visible chemical decomposition ensues. At first a considerable current will be indicated by the galvanometer; the deflection soon diminishes, however, and finally becomes very small, though this small current seems to leak through permanently.

If, instead of using a single Daniell's cell, we employ some source of electromotive force which can be varied as we please, and gradually raise its intensity, we shall find, when it exceeds a certain value, about 1.7 volt, that a permanent current of considerable strength flows through the solution, and, after the initial period, shows no signs of decrease. This current is accompanied by chemical decomposition.

Now let us disconnect the platinum plates from the battery, and join them directly with the galvanometer. A current will flow for a while in the reverse direction; the system of plates and acidulated water through which a current has been passed, acts as an accumulator, and will itself yield a current in return.

These phenomena are explained by the existence of a reverse electromotive force at the surfaces of the platinum plates. Only when the applied electromotive force exceeds this reverse force of polarization, will a permanent steady current pass through the liquid, and visible chemical decomposition proceed.

Recent experiments, by Le Blanc, Oberbeck, and others, have shown that the reverse electromotive force of polarization is due to the deposit on the electrodes of minute quantities of the products of chemical decomposition. Differences between the two electrodes

are thus set up, and, if disconnected from the external electromotive force, the arrangement would act as a source of current, just as does a primary cell. When acted on by the external electromotive force, the effect of the deposits is to oppose a reverse electromotive force to that in the external circuit. As the primary current continues to pass, the densities of the deposits increase, and with them grows the reverse electromotive force, till a continuous film of deposit is formed. This film has, by calculation from the total electric transfer needed to produce it, a thickness of the order of  $10^{-8}$  centimetre—a new measurement of the thickness of a layer of molecular dimensions. The reverse electromotive force of polarization then reaches its maximum value. If the primary external electromotive force be not as great as this maximum reverse force, the maximum value is, of course, not reached; the polarization grows till the reverse electromotive force is sensibly equal to that applied, and the current nearly stops. The slight leakage current which remains is probably due to the gradual diffusion away from the electrodes of the products of the decomposition. If the applied electromotive force be greater than the maximum force of polarization, a permanent current flows, but the effective electromotive force of the circuit is only the excess of the applied force  $E$  over the reverse force  $E'$ , the current being  $(E - E')/R$ .

In the case we have chosen, hydrogen and oxygen are evolved from acidulated water at the surfaces of bright platinum electrodes. In contact with these two gases respectively, the system will act as an accumulator, and continue to give a reverse current till the gases are exhausted. Now the maximum reverse force of polarization, about 1.7 volt, is greater than the electromotive force which the polarized plates themselves exhibit when used as a source of current. It seems that the process is not reversible in the thermodynamic sense of the word. If, however, the electrodes be covered by a deposit of platinum black, by previously passing a current backwards and forwards between them through a solution of platinum chloride, Le Blanc has shown that the minimum decomposition point is 1.07 volt, which is equal to the electromotive force of the oxyhydrogen gas battery. In this case, then, the process is reversible. If an external electromotive force of 1.07 volt be applied, the system is in equilibrium; while, if the applied

force exceeds or falls short of that value by an infinitesimal amount, an indefinitely small current will pass one way or the other, and the gases are slowly evolved or absorbed. The platinum black has a very large surface, and, owing to the well-known occluding power of platinum, the gases are probably absorbed in the electrodes as fast as they are produced. They diffuse through the substance of the electrodes, and dissolve in the liquid or escape into the atmosphere. On the other hand, when bright plates are used, the exposed surface is too small to absorb the gases, which must therefore be evolved directly as bubbles at the plates. In this process a certain amount of irreversible work is done, and the applied electromotive force rises to 1.7 volts before it can overcome the opposing force.

By methods we shall describe later, it is possible to separate the potential-differences at the anode and the cathode, and, although some doubt remains as to the trustworthiness of the absolute values, the results may fairly be used when absolute values are not necessary. It has been concluded from several series of experiments that, in the case of all substances examined, the deposition and solution of metals in contact with solutions of their salts, are reversible processes—the decomposition voltage is equal to the reverse electromotive force which the metal itself gives when going into solution.

**78.** During the early investigation of the subject, it was thought that, since hydrogen and oxygen were usually evolved, the electrolysis of solutions of acids and alkalis was to be explained as a direct decomposition of water, the function of the acid or alkali being imagined simply to be to give conductivity to the otherwise non-conducting solvent. When salt solutions are examined, other substances, such as metals, are deposited at the electrodes, and it is necessary to suppose that the solute itself takes part in the process of conduction. During the electrolysis of a solution of copper sulphate, copper is deposited at the cathode, and copper is dissolved from a copper anode, or oxygen and sulphuric acid liberated if the anode be of platinum. These phenomena are explained readily by the hypothesis that the ions are a positively electrified copper atom, which may be written as  $\text{Cu}^+$ , and the negatively electrified acid group  $\text{SO}_4^-$ , which

combines with copper, or, if no dissolvable metal be present, attacks water to form  $\text{H}_2\text{SO}_4$  and oxygen. No facts are known in this case inconsistent with such a view of the process; but, in solutions in some other solvents, a similar supposition seems insufficient. It is well to remember that the simple case of copper sulphate is also explicable on the theory that the ions result from the dissociation of a complex molecule formed by the combination of the salt and the water. The ions  $\text{Cu}^+(\text{H}_2\text{O})$  and  $\text{SO}_4^-(\text{H}_2\text{O})$  would produce exactly the same phenomena as those to be expected from the action of the simpler structures, and the same effects would result if the charged particles were associated with a number of of water molecules.

A study of the products of decomposition alone does not lead necessarily to a knowledge of the ions involved in the passage of the current through the electrolyte. The electric force is active throughout the whole solution; all the ions must come under its influence and therefore move, but some may need a smaller electromotive force than others for their evolution at the electrode, and consequently, as long as any quantity of all the ions of the solution remains in the layer of liquid next the electrode, only these ions will be evolved.

The issue is obscured in another way also. When the ions are set free at the electrodes, they may unite with the substance of the electrode or some constituent of the solution and form secondary products. For instance, there is reason to suppose that, in a dilute solution of sulphuric acid, the ions either are or contain hydrogen and the acid group  $\text{SO}_4$ . The ion  $\text{SO}_4$ , however, when it reaches the anode attacks the water, produces a molecule of  $\text{H}_2\text{SO}_4$ , and liberates oxygen.

An interesting example of secondary action is furnished by the common technical process of electroplating with silver from a bath of potassium silver cyanide. The operation has been studied by Hittorf among others, who holds that the cation is potassium, and the anion the group  $\text{AgCy}_2$ . Each K ion, as it reaches the cathode, precipitates silver by reacting with the solution in accordance with the equation

while the anion  $\text{AgCy}_2$  dissolves an atom of silver from the anode, and re-forms the complex cyanide  $\text{KAgCy}_2$  by combining with the  $2\text{KCy}$  produced in the reaction described by the above equation. If the anode consist of platinum, cyanogen gas is evolved thereat from the anion  $\text{AgCy}_2$ , and the platinum becomes covered with the insoluble silver cyanide  $\text{AgCy}$ , which soon stops the current. The coating of silver obtained by the process described above is coherent and homogeneous, while that deposited from a solution of silver nitrate, as the result of the primary action of the current, is crystalline and easily detached.

The corresponding cyanide process in the case of gold is now extensively used for the extraction of gold from its ores. The rock, containing small quantities of gold in a state of very fine division, is treated with potassium cyanide, and the solution of the double cyanide obtained in this way is electrolysed between steel anodes and lead cathodes. Prussian blue, which is again worked up into potassium cyanide, is formed on the anodes, and the gold is removed from the lead cathodes by cupellation.

Many organic compounds can be prepared synthetically by taking advantage of secondary actions at the electrodes, such as reduction by the cathodic hydrogen, or oxidation at the anode.

The injurious effects of polarization in primary batteries led to many attempts to overcome it. The methods in use in the common form of cell are well known, and have been described in § 36, Chapter V.

**79.** Davy had shown previously that there was no accumulation of electricity in any part of a voltaic circuit, and that a uniform flow or current existed throughout. Faraday set himself to examine the relation between the strength of this current and the amount of chemical decomposition. He first proved by observations on the decomposition of acidulated water, that the amount of chemical action in each of several cells was the same when the cells were joined together and a current passed through them all in series, even if the sizes of the platinum plates were different in each. The volume of hydrogen was unchanged, even if electrodes of different materials—such as zinc or copper—were used. He then divided the current after it had passed

Faraday's  
Laws.

through one cell into two parts, each of which passed through another cell before being reunited. The sum of the volumes of the gases evolved in these two cells was equal to the volume evolved in the first cell. The strength of the acid solution was then varied, so that it was different in the different cells in one series, but the chemical action still remained the same in all. Thus the induction known as Faraday's first law was made:—

The amount of decomposition is proportional to the quantity of electricity which passes.

An apparatus for the decomposition of water can therefore be used to measure the total quantity of electricity which has passed round a circuit. Such instruments are termed *voltameters*.

The same law was then shown to be true for solutions of various metallic salts, and also for salts in a state of fusion—the weight of metal deposited being always the same for the same quantity of electricity. When the relative masses of the deposits of different substances by the same current were examined, a most important result appeared, which may be formulated as Faraday's second law:—

The mass of any substance liberated by a definite quantity of electricity is proportional to the chemical equivalent weight of the substance. In the case of elementary ions, this equivalent weight is the atomic weight divided by the valency, and, in the case of compound ions, it is the molecular weight divided by the valency.

It was then proved that the amount of zinc consumed in each cell of the battery was identical with that deposited by the same current in an electrolytic cell placed in the external circuit.

Faraday's work laid the foundations of the modern quantitative science of electrolysis. His results can be gathered into one statement, as follows:—

The quantity of a substance which separates at an electrode is proportional to the whole amount of electricity which passes, and to the chemical equivalent weight of the substance.

80. An accurate confirmation of Faraday's law for solutions of silver salts has been effected incidentally in the course of many experimental determinations of the electro-chemical equivalent of silver. If the value obtained

for the silver deposited by unit quantity of electricity be the same when the strength of current and the other conditions of the experiment are varied, the quantity of electricity and the mass of silver deposited must be proportional to each other. An exact knowledge of the electrochemical equivalent of silver is of great importance, since, given this constant, a silver voltameter can be used as a means of measuring accurately the total quantity of electricity, or the average current, which has passed through a circuit.

In order to determine the electrochemical equivalent, a constant current, which is measured simultaneously in absolute electromagnetic units (see § 62, Chapter VIII), is passed for a measured time through a solution of some silver salt. The most constant results are obtained when a neutral solution of the nitrate is used, containing about fifteen parts of salt to one hundred of water, and the current has an intensity of about one hundredth of an ampere to the square centimetre. The silver may be deposited on a platinum bowl used as cathode, the anode being a silver plate wrapped in filter paper to catch any particles disintegrated. The electrochemical equivalent is expressed as the number of grams of silver deposited by a current of one ampere in one second.

The mean result of the best determinations is about 0.001118 or 0.001119 gram per ampere-second. As we have stated (p. 181), the practical definition of the ampere assumes the value 0.001118.

The corresponding constant for other elements or compounds can be calculated from this number by dividing it by the chemical equivalent of silver, viz. 107.9, and multiplying by the chemical equivalent of the substance required. The value of hydrogen thus comes out  $1.044 \times 10^{-5}$ , its atomic weight being taken as 1.008, when oxygen is 16.

It will be noticed that the chemical constant involved is the equivalent, and not the atomic weight. Therefore, in the case of substances like iron, which form two series of salts, the amounts deposited will be different when solutions of the different salts are used. The two amounts will be in the proportion of the two chemical equivalents; if a current be sent through solutions of a ferric and a ferrous salt in series, the resultant weights will be as  $56/3 : 56/2$ .

With no substance other than silver have such accurate experimental results been obtained, though many observations have been made on other bodies, solid and gaseous. In all cases, Faraday's laws have been found to be true within the limits of experimental error, and we may calculate electrochemical equivalents from the measured value for silver and the known chemical equivalents of the different ions. Kohlrausch and Holborn, in their book 'Das Leitvermögen der Elektrolyte,' give a list of equivalent and electrochemical equivalent weights, the experimental value for silver being taken as 1.118 mg./amp.-sec.

*Equivalent weights  $A$  ( $\frac{1}{2}\text{O} = 8.00$ ), and electrochemical equivalents  $E$  in mg./amp.-sec.) of mono- and di-valent ions.*

Solvents other than water, for example acetone, pyridine, liquified hydrogen chloride, etc. have also been used. Faraday's laws hold good in such cases, and the electrochemical equivalents seem to be identical with those obtained when the solvent is water. Faraday's laws have also been demonstrated for fused salts, many of which are good electrolytes, with conductivities of the same order as those of aqueous solutions.

Again, in recent years it has been shown that, in certain cases, the discharge of electricity through gases is an electrolytic process accompanied by chemical decomposition. Here also the corresponding amount of electric transfer is accompanied by the same amount of chemical separation—the electrochemical equivalents are the same for gaseous electrolytes as for solutions.

In every case of electrolysis, Faraday's laws seem to apply, and the amount of a given substance liberated by a given transfer of electricity appears to be the same under all conditions. This result leads to an exact view as to the nature of the process. Since the amount of substance deposited is proportional to the quantity of electricity which passes, it follows that a definite charge of electricity is associated with a definite mass of the substance. We are thus led to look on the passage of an electric current through a solution as due to the carriage by moving parts of the electrolyte of opposite electric charges in opposite directions through the liquid. Each ion carries with it a fixed charge of electricity, positive or negative, which is given up to the electrode under the influence of an electromotive force above a certain limit. It is clear that, on this convective view of electrolysis, the conductivity of a solution must be proportional to the charge on each ion, to the number of ions, and to the velocity with which they move through the solution.

Whenever one gramme-atom or gramme-molecule of any monovalent ion is separated at an electrode, the same quantity of electricity passes round the circuit; when the ion is divalent, the quantity is twice as great, and so on. All monovalent ions must therefore be associated with the same charge, all divalent ions with twice that charge, etc.

The quantity of electricity involved is easily calculated by considering an example. If a current of one ampere flows for one second, experiment shows that 0.001118 of a gramme of silver is liberated from the solution of one of its salts. Thus, when the equivalent weight in grammes is deposited, the quantity of electricity passing is  $107.92/0.001118$  or 96530 ampere-seconds or coulombs. The same result is of course true for the gramme-equivalent of any other substance, the gramme-equivalent being the gramme-molecule or gramme-atom divided by the valency. Whenever a

gramme-equivalent of a substance is decomposed, therefore, 96530 coulombs of electricity pass round the circuit, and, as we shall prove later, this is the amount of charge actually transported through the electrolyte by one gramme-equivalent of any ion.

It is possible to calculate approximately the absolute electric charge carried by a single monovalent ion, since the number of molecules in a given volume of gas can be estimated by aid of the kinetic theory. As a mean value, at  $0^{\circ}\text{C}$ . and normal atmospheric pressure, there exist about  $6 \times 10^{19}$  molecules in one cubic centimetre of any gas.

As we have seen, one electromagnetic unit of electricity evolves  $1.044 \times 10^{-4}$  gramme of hydrogen, which at normal temperature and pressure fills a volume of 1.16 c.c., and therefore contains about  $7 \times 10^{19}$  molecules or  $1.4 \times 10^{20}$  atoms, and yields the latter number of ions when dissolved as a hydrogen salt. Each ion is then associated with  $7.1 \times 10^{-21}$  electromagnetic units. The ratio between the units of electric quantity being  $3 \times 10^{10}$ , the ionic charge is about  $2.1 \times 10^{-10}$  electrostatic units.

In a future chapter on the conduction of electricity through gases, we shall describe experiments by which the absolute charge on a gaseous ion may be estimated. The value obtained is about  $3.4 \times 10^{-10}$  electrostatic units—identical within the limits of error with the absolute charge on an ion in liquid electrolytes.

Thus, the electric charge on a single monovalent ion seems to be a true natural unit, and the results we have summarized lead to an atomic theory of electricity. As von Helmholtz has said, "If we accept the hypothesis that the elementary substances are composed of atoms, we cannot avoid concluding that electricity also is divided into definite elementary portions, which behave like atoms of electricity."

81. The current through a metallic conductor is, to a very great degree of accuracy, proportional to the electromotive force applied. As we have seen, this relation, known as Ohm's law, may be expressed in the form that  $c = E/R$ , where  $R$  is a constant for any given conductor under fixed conditions, and is called its resistance. The law is verified if the resistance be shown to be independent of the current passing

The conductivity of electrolytes.

through it. The early experimenters, in the course of their investigations, made efforts to discover whether electrolytes also conformed to Ohm's law. It was known that, owing to the reverse force of polarization, no permanent current of moderate intensity could be maintained through an electrolyte unless the electromotive force exceeded a certain limit; but polarization occurs, primarily at any rate, at the electrodes, and it remained to see, when all reverse forces at the electrodes were eliminated, whether the flow of the current in the body of the liquid was in accordance with the law. Eventually Prof. F. Kohlrausch, who is now the Director of the German National Physical Laboratory—the great *Physikalische Reichsanstalt* at Charlottenburg near Berlin—proved that solutions have a real resistance, which remains constant when measured with various currents and by different methods.

The current in a circuit containing a electrolytic cell can therefore be calculated by Ohm's law, if, from the total electromotive force of the circuit, be subtracted the reverse electromotive force due to the polarization of the electrodes and to any changes produced by the current in the nature and concentration of different parts of the solution.

**82.** Owing to the difficulties introduced by polarization, the

**Experimental  
methods.**

resistance of an electrolyte cannot be measured by the continuous current methods adopted in the case of metallic conductors; it is necessary, in some way, to eliminate the effects of the reverse electromotive force at the electrodes. Many attempts were made before a satisfactory mode of experiment was devised, and developed into a convenient method.

If, instead of using continuous currents, we pass currents which alternate in direction through a solution, the products of the decomposition deposited on the electrodes by the passage of the current in one direction are removed by the reversed current which follows immediately. If the alternations be rapid enough, the quantity of substance deposited during each rush of current is very small. Moreover, when deposition first begins, and we are still far from the limiting value of the polarization, the reverse electromotive force is proportional to the surface density of the deposit. It may therefore be diminished again by increasing the

area of the electrodes, and spreading the products of the decomposition over larger areas. The area of a platinum plate is increased enormously if we coat it with platinum black. In order to do this, a current is passed backwards and forwards between two electrodes through a solution of platinum chloride. By using currents which alternate rapidly, and electrodes coated with platinum black, the effects of polarization may be made insensible in our measurements of resistance.

With the usual form of Wheatstone's bridge, alternating currents would give no deflection of the galvanometer, and some modification is required. Kohlrausch used a telephone as indicator in place of the galvanometer; a rapidly alternating current gives a buzzing sound in the telephone, and the bridge is adjusted till this sound disappears, or is a minimum. The alternating currents may be obtained by the use of a small induction coil, or by passing the current of an alternating electric supply system through a suitable transformer to give an electromotive force of a few volts at most. The most usual form of apparatus is shown in Figure 99.

Fig. 99.

The metre bridge is adjusted till no sound is heard in the telephone, when the well-known relation between the resistances of the four arms of the bridge holds good.

The telephone is not a very pleasant instrument to use in this way, and a modification of the method is more rapid and also more accurate. The current from one or more dry cells is led to an ebonite

drum, turned by a motor or a hand-wheel. On the drum are fixed brass strips with wire brushes touching them in such a manner that the current is reversed several times in each revolution. The wires from the drum are connected with an ordinary resistance box in the same way as the battery wires of the usual Wheatstone's bridge. A moving coil galvanometer is used as indicator, and on the other end of the drum there is another set of strips, arranged to reverse periodically the connexions of the galvanometer, so that any residual current which flows through it is direct and not alternating. These strips are rather narrower than the first set, and thus the galvanometer circuit is made just after the battery circuit is made, and broken just before the battery circuit is broken. The high moment of inertia of the galvanometer coil makes its period of swing very slow compared with the period of alternation of the current, and therefore the slight residual effects of polarization and other periodic disturbances are prevented from sensibly affecting the galvanometer. When the measured resistance is not altered by increasing the speed of the commutator, or changing the ratio of the arms of the bridge, the disturbing effects may be considered to be eliminated.

The form of vessel chosen to contain the electrolyte depends on the order of resistance to be measured. For dilute solutions the shapes of Figures 100 and 101 will be found convenient, while for more concentrated solutions those indicated in Figures 102 and 103 are suitable.

Fig. 100.

Fig. 101.

The absolute resistances of certain solutions have been determined by Kohlrausch by comparison with mercury, and, by using

one of these solutions in any cell, the constant of that cell can be found once for all. From the observed resistance of any given

Fig. 102.

Fig. 103.

solution in the cell, the resistance of a centimetre cube, or the specific resistance, can then be calculated. The reciprocal of this, or the conductivity, is a more generally useful constant; it is conveniently expressed in terms of a unit equal to the reciprocal of an ohm.

As the temperature coefficient of conductivity is large, usually about two per cent. per degree, it is necessary to place the resistance cell in a paraffin or water bath, and observe its temperature with some accuracy.

**83.** Kohlrausch expressed his results in terms of equivalent conductivity, that is, the conductivity  $k$  divided by the number  $n$  of gram-equivalents of electrolyte per litre. As the concentration of solutions of monovalent salts, such as potassium chloride, sodium nitrate, etc., diminishes, the value of  $k/n$  approaches a limit, and, if the dilution be carried far enough in water distilled repeatedly, becomes constant, that is to say, at great dilution the conductivity is proportional to the concentration.

The general result of these experiments can be represented graphically by plotting  $k/n$  as ordinates, and  $n^{\frac{1}{2}}$  as abscissæ;  $n^{\frac{1}{2}}$  is a number proportional to the reciprocal of the average distance between the molecules, to which it seems likely that the equivalent conductivity will be related. The general forms of the curves for the neutral salt of a monovalent acid and for a caustic alkali or monovalent acid (like hydrochloric acid) are shown in Fig. 104. The curve for the neutral salt comes to a limiting value, while that for the acid or alkali attains a maximum at a certain very small con-

centration, and falls again when the dilution is pushed to extreme limits. The meaning of this fall still remains to be elucidated. In some solvents the form of both these curves is entirely different.

Fig. 104.

The values of the equivalent conductivities of all neutral salts dissolved in water are, at great dilution, of the same order of magnitude, while those of acids at the maximum are about three times as great.

Passing to salts of divalent acids and other more complicated electrolytes, we find it impossible to reach such definite limiting values for the equivalent conductivity as are given by monovalent salts. Moreover, the influence of increasing concentration is more marked, the curves sloping at much larger angles. These changes in the phenomena are still greater when, as in copper sulphate, both metal and acid are divalent, and greatest of all in such substances as ammonia and acetic acid, which have very small conductivities when dissolved in water.

**84.** As we saw in the last chapter, the experimental relations summarized in Faraday's laws indicate that electrolysis is to be considered as a process resembling convection, a constant stream of cations moving with the current, and a stream of anions in the opposite direction. The quantity of electricity thus conveyed will be proportional to the number of carriers and to the speed with which they travel.

If we pass a current between copper plates through a solution of copper sulphate, the colour of the liquid in the neighbourhood of

The migration  
of the ions  
and transport  
numbers.

the anode becomes deeper, and in the neighbourhood of the cathode lighter in shade. This is well seen if the electrodes be arranged horizontally with the anode underneath. When the electrodes are of copper, the quantity of metal in solution remains constant, since it is dissolved from the anode as fast as it deposited at the cathode, but, if we use platinum electrodes, the amount in solution continually becomes less. More salt is taken from the neighbourhood of the cathode than from the anode, and the colour of the solution becomes pale more rapidly near the cathode than near the anode.

This subject was first investigated systematically by Hittorf, who examined many solutions in a manner which enabled the liquid round the two electrodes to be analysed separately after the passage of the current.

We will assume at first that the ions are simple, or, at all events, that the opposite ions are associated with equal amounts of solvent or salt. If the opposite ions move with equal velocities, the result of the passage of the current will be that, while the composition of the middle portion of the solution remains unaltered, the products of the decomposition, which appear at the electrodes, are taken in equal proportions from the solution surrounding the anode, and from that round the cathode. If, however, one of the ions travels faster than the other, it will get away from the portion of the solution whence it comes more quickly than the other ion enters. When the electrodes are of non-dissolvable material, therefore, the concentration of the liquid in this region will fall faster than in that round the other electrode.

Let us assume that the cation drifts to the right with a velocity  $u$ , and the anion to the left with a velocity  $v$ . The velocity of the cation can be resolved into  $\frac{1}{2}(u+v)$  and  $\frac{1}{2}(u-v)$ , and the velocity of the anion into  $\frac{1}{2}(v+u)$  and  $\frac{1}{2}(v-u)$ . On pairing these components, we have a drift of the two ions right and left, each with a speed  $\frac{1}{2}(u+v)$ , involving no accumulation at the electrodes, and a uniform flow of the electrolyte itself without separation with a speed  $\frac{1}{2}(u-v)$  to the right.

Thus at the cathode there is a gain of electrolyte equal to  $\frac{1}{2}(u-v)$ , and a loss, due to electrolytic separation, of  $\frac{1}{2}(u+v)$ : a total loss of  $v$ . At the anode there is a loss of  $\frac{1}{2}(u-v)$  and a loss of

$\frac{1}{2}(u+v)$ , a total loss of  $u$ . The initial losses of electrolyte at the two electrodes, then, before diffusion sensibly affects the result, are in the same ratio as the velocities of the ions travelling away from them.

The process can be illustrated clearly by a method due to

Fig. 105.

Hittorf. In Fig. 105 the black dots represent the one ion, and the white circles the other. If the black ions move to the left twice as fast as the white ions move to the right, the black ions will move over two of our spaces while the white ones move over one. Two of these steps are represented in the diagram. At the end of the process it will be found that six molecules have been decomposed, six black ions being liberated at the left and six white ions at the right. Looking at the combined molecules, however, we see that while five remain on the left side of the middle line, only three are still present on the right. The left-hand side, towards which the faster ions moved, has lost two combined molecules, while the right-hand side, towards which the slower ions travelled, has lost four—just twice as many. Thus we see that the ratio of the masses of salt lost by the two sides is the same as the ratio of the velocities of the ions leaving them. Therefore, on the assumption that no unsymmetrical complex ions are present, by analysing the contents of a solution after a current has passed, we can calculate the ratio of the velocities of its two ions. Hittorf called the phenomenon the “migration of the ions,” and expressed his results in terms of a transport number, or migration constant, which gives the amount of salt taken from the neighbourhood of the cathode as a fraction of the whole amount that disappears. If there be no unsymmetrical complex ions, it also expresses the ratio of the velocity of the anion to the sum of the opposite ionic velocities.

The following table gives the transport numbers for some few salts; the concentration of the solutions being expressed as the number of gramme-equivalents per litre.

*Transport Numbers.*

$n =$	0.01	0.1	1.0	2.0
KCl	0.506	0.508	0.514	0.515
AgNO <sub>3</sub>	0.528	0.528	0.501	0.476
NaOH	—	0.82	0.825	—
HCl	—	0.172	0.176	0.185
$\frac{1}{2}$ CdI <sub>2</sub>	0.56	0.71	1.12	1.22
$\frac{1}{2}$ CuSO <sub>4</sub>	—	0.632	0.696	0.720
$\frac{1}{2}$ H <sub>2</sub> SO <sub>4</sub>	—	0.191	0.174	0.168

The transport numbers for cadmium iodide, which, for solutions of more than half normal concentration, are greater than unity, show that the cathode vessel loses more salt than the whole solution does. It follows that some unaltered salt must travel through the solution towards the anode, and this result at once led to the conception of complex anions of the type I (CdI<sub>2</sub>). The changes with concentration in the transport number of many other substances, such as calcium chloride and copper sulphate, seem too great to be explained by a different rate of variation of the quasi-frictional resistance which the solution offers to the passage of the two ions, and suggest that similar unsymmetrical complex ions may exist in many solutions.

85. A further step was taken in the year 1879 by Kohlrausch, who showed that a knowledge of the conductivity of a solution enables the sum of the opposite ionic velocities to be calculated. We have seen that we can represent the facts by considering the process of electrolysis to be a kind of convection, the ions moving through the solution and carrying their charges with them. Each monovalent ion may be supposed to carry a certain definite charge, which we can take to be the ultimate indivisible unit of electricity; each divalent ion carries twice that amount, and so on.

Let us consider, as an example, the case of an aqueous solution of potassium chloride, of which the concentration is  $m$  gramme-

equivalents per cubic centimetre. There will then be  $m$  gramme-equivalents of potassium ions and the same number of chlorine ions in this volume. Let us suppose that on each gramme-equivalent of potassium there reside  $+e$  units of electricity, and on each gramme-equivalent of chlorine ions  $-e$  units. If  $u$  denote the average velocity of the potassium ions, the positive charge carried per second across unit area normal to the flow is  $meu$ . Similarly, if  $v$  be the average velocity of the chlorine ions, the negative charge carried in the opposite direction is  $mev$ . But positive electricity moving in one direction is equivalent to negative electricity moving in the other, so that the total current is  $me(u+v)$ .

Now let us consider the amounts of potassium and chlorine liberated at the electrodes by this current. At the cathode, if the chlorine ions were at rest, the excess of potassium ions would be the number arriving in one second, viz.  $mu$ . But, since the chlorine ions move also, a further separation occurs, and  $mv$  potassium ions are left without partners. The total number of gramme-equivalents liberated therefore is  $m(u+v)$ . Now, by Faraday's law, the liberation of one gramme-equivalent of any ion involves the passage of a definite quantity  $Q$  of electricity round the circuit. Thus, the total quantity passing in one second, that is the current, is  $mQ(u+v)$ . On comparing this result with the first expression for the same current, it follows that the charge,  $e$ , on one gramme-equivalent of either ion is equal to the quantity of electricity passing round the circuit when the gramme-equivalent is liberated.

We know that Ohm's law holds good for electrolytes, so that the current is also given by  $-kdV/dx$ , where  $k$  denotes the conductivity of the solution, and  $-dV/dx$  the potential gradient, *i.e.* the fall in potential per unit length along the lines of current flow.

$$\text{Thus} \qquad me(u+v) = -k \frac{dV}{dx};$$

$$\text{or} \qquad u+v = -\frac{k}{me} \cdot \frac{dV}{dx},$$

an equation in which everything may be expressed in centimetre-gramme-second units. By measuring  $1/k$  in ohms (an ohm being

$10^9$  C.G.S.),  $e$  in coulombs ( $10^{-1}$ ), and writing  $n$  for the number of gramme-equivalents of solute per litre instead of per cubic centimetre, we get

$$u + v = -10^{-5} \frac{k}{ne} \cdot \frac{dV}{dx}.$$

Now  $e$  is 96530 coulombs; so that for a potential gradient of 1 volt per centimetre ( $10^8$  C.G.S. units), we have

$$u_1 + v_1 = 1.036 \times 10^{-2} \times \frac{k}{n}$$

which gives the relative velocity (or the sum of the opposite velocities) of the two ions in centimetres per second under unit potential gradient. These numbers,  $u_1$  and  $v_1$ , measure what we may call the mobilities of the two ions.

Since the transport numbers give us the ratio of the ionic velocities if no unsymmetrical complex ions are present, we can deduce the absolute values of  $u_1$  and  $v_1$  from this theory. Thus, for instance, the conductivity of a solution of potassium chloride, containing one-tenth of a gramme-equivalent per litre, is 0.01119 of a reciprocal ohm at  $18^\circ$  C. Therefore

$$\begin{aligned} u_1 + v_1 &= 1.037 \times 10^{-2} \times 0.1119 \\ &= 0.001165 \text{ cm. per sec.} \end{aligned}$$

Hittorf's experiments show us that the ratio of the velocity of the anion to that of the cation in this solution is .51 : .49. The absolute velocity of the chlorine ion under unit potential gradient is therefore 0.000595 cm. per sec., and that of the potassium ion 0.000570 cm. per sec. Similar calculations can be made for solutions of other concentrations and of other salts. An examination of the results shows that, in general, the velocities of the ions increase as the concentrations of the solutions diminish, and, at great dilution, the velocity of an ion in the solution in water of a simple binary salt is independent of the nature of the other ion present. From

K	$67 \times 10^{-5}$	Cl	$70 \times 10^{-5}$
Na	45 "	I	70 "
Li	36 "	NO <sub>3</sub>	65 "
NH <sub>4</sub>	67 "	OH	184 "
H	323 "	C <sub>2</sub> H <sub>3</sub> O <sub>2</sub>	36 "
Ag	58 "	C <sub>3</sub> H <sub>5</sub> O <sub>2</sub>	33 "

this result we may deduce the existence of specific ionic mobilities, the values of which are given in the table for different monovalent ions in centimetres per second per volt per centimetre.

**86.** Sir Oliver Lodge was the first to measure directly the velocity of transport of an ion. In a horizontal glass tube connecting two vessels filled with dilute sulphuric acid he placed a solution of sodium chloride in solid agar-agar jelly. This solid solution was made alkaline with a trace of caustic soda to bring out the red colour of a little phenolphthalein added as indicator. A current was then passed from one vessel to the other along the tube. The hydrogen ions from the anode vessel of acid were thus carried along the tube, and decolorized the phenolphthalein as they travelled. By this method the velocity of the hydrogen ion through a jelly solution under a known potential gradient could be observed. The results of three experiments gave 0.0029, 0.0026, and 0.0024 cm. per sec. as the velocity of the hydrogen ion for a potential gradient of one volt per centimetre. Kohlrausch's number is 0.0032 for the dilution corresponding to maximum conductivity.

The velocities of other ions have been determined directly in another way by the present writer. Two solutions, having one ion in common, of equivalent concentrations, different densities, different colours, and nearly equal specific resistances, were placed one over the other in a vertical glass tube. An improvement on the original apparatus is shown in Fig. 106. The lighter solution is placed in the U tube, and the denser solution then run in below it. We may use, as an example, decinormal solutions of potassium carbonate and potassium bichromate. The colour of the latter is due to the presence of the bichromate group,  $\text{Cr}_2\text{O}_7$ . When a current is passed across the junction, the anions  $\text{CO}_3$  and  $\text{Cr}_2\text{O}_7$  travel in the direction opposite to that of the current, and their velocity may be determined by measuring the rate at which the colour boundary moves. The mobility

Fig. 106.

of an ion is found to be very little less in a solid jelly than in an ordinary liquid solution. The velocities may be measured therefore by tracing the change in colour of an indicator, or the formation of a precipitate. Thus decinormal jelly solutions of barium chloride and sodium chloride, the latter containing a trace of sodium sulphate, may be placed in contact. Under the influence of an electromotive force, the barium ions move up the tube, and their presence is shown by the trace of insoluble barium sulphate formed. By keeping the conductivities of the two solutions nearly the same, discontinuity of potential gradient may be avoided, and the gradient may then be calculated from the area of cross-section of the tube, the conductivity of the solution, and the strength of the current as measured with a galvanometer.

These methods have been improved and extended by Orme-Masson and B. D. Steele. The general results confirm the results of Kohlrausch's theory for simple binary salts. In solutions of more complicated electrolytes, the presence of unsymmetrical complex ions is suggested by other evidence, and the concordance of the direct measurements with Kohlrausch's theory is less exact.

As the concentration of dilute aqueous solutions increases, the conductivity falls, and the calculated ionic velocities with it. The direct measurements confirm this decrease of velocity and verify the calculation in the case of simple binary electrolytes. The diminution of conductivity may be due to an increase of the frictional resistance offered by the liquid to the passage of the ions, to part of the solute failing to be ionized, or to a combination of these causes. If we assume that the second cause alone is involved, the fraction  $\alpha$  of the electrolyte ionized will be given by the ratio between the equivalent conductivity  $\lambda$  of the solution, and its value  $\lambda_{\infty}$  at infinite dilution. But it is important to remember that, only on the assumption named, may we write

$$\alpha = \frac{\lambda}{\lambda_{\infty}}.$$

87. When two metallic conductors are placed in an electrolyte, a current will flow through a wire connecting them provided that a difference of any kind exists between

the two conductors in the nature either of the metals or of the portions of the electrolyte which surround them. A current can be obtained by the combination of two metals in the same electrolyte, of two metals in different electrolytes, of the same metal in different electrolytes, or of the same metal in solutions of the same electrolyte at different concentrations.

In order that the current should be maintained, and the electromotive force of the cell remain constant during action, it is necessary to insure that the changes in the cell, chemical or other, which produce the current, should neither destroy the difference between the electrodes, nor coat either electrode with a non-conducting layer through which the current cannot pass. As an example of a successful cell of fairly constant electromotive force, we may take that of Daniell, which consists of the electrical arrangement

zinc / zinc sulphate solution / copper sulphate solution / copper, the two solutions being usually separated by a pot of porous earthenware. When the zinc and the copper plates are connected through a wire, a current flows, the conventionally positive electricity passing from copper to zinc in the wire and from zinc to copper through the cell. Zinc dissolves, and zinc replaces an equivalent amount of copper in solution, copper being deposited simultaneously on the copper electrode. The internal rearrangements which accompany the production of a current do not cause any change in the original nature of the electrodes, and, as long as a moderate current flows, the only variation in the cell is the appearance of zinc sulphate on the copper side of the porous wall. While the supply of copper sulphate is maintained, copper, being more easily separated from its solution than zinc, is deposited alone at the cathode, and the cell remains constant. On the other hand, if no current be allowed to flow, slow processes of diffusion, unchecked by migration in the opposite direction, will cause copper to appear in the anode vessel, and finally to be deposited on the zinc. Little local galvanic cells are thus formed on the surface of the zinc, which then dissolves, even though the circuit of the main cell is not completed. Till this deposition occurs, the cell can be left no open circuit without waste, and no zinc will dissolve if it is

chemically pure. If, however, commercial zinc, which contains iron, be used, local action is again set up. This action can be prevented by amalgamating the zinc; probably because that process produces a uniform surface, iron being insoluble in mercury.

88. Considered thermodynamically, galvanic cells must be divided into reversible and non-reversible systems. Reversible  
cells. If the slow processes of diffusion be ignored, the Daniell cell already described may be taken as a type of a reversible cell. Let an electromotive force exactly equal to that of the cell be applied to it in the reverse direction. When the applied force is diminished by an infinitesimal amount, the cell produces a current in the usual direction, and the ordinary chemical changes occur. If the external electromotive force exceeds that of the cell by ever so little, a current flows in the opposite direction and all the former chemical changes are reversed, copper dissolving from the copper plate, while zinc is deposited on the zinc plate. The cell, together with this balancing electromotive force, is thus a reversible system in true equilibrium, and the thermodynamical reasoning applicable to such systems can be used to examine its properties.

Cells from which gas is lost into the atmosphere, such as Volta's original couple, zinc / dilute acid / copper, and others in which irreversible processes of reduction occur, such as the Grove arrangement, zinc / dilute sulphuric acid / nitric acid / platinum, form essentially irreversible systems. Moreover, it does not follow that, because an accumulator can be used to give a current in the reverse direction to the charging current, it is, in the thermodynamic sense, a reversible cell. This is only the case when an electromotive force greater by an indefinitely small amount than the secondary electromotive force of the cell will reverse the current through it and the chemical actions in it also. For this to be possible, it is necessary that the whole of the energy of the charging current should be put into available energy of chemical separation, which can all be regained when the cell is discharged.

Let us imagine that a reversible cell, balanced by an equal and opposite electromotive force, is put through a thermodynamic cycle

of changes, after the manner of Carnot's engine. Let us draw an indicator diagram with ordinates denoting the electromotive force  $E$  of the cell, and abscissæ representing the electric transfer through the system. Let the system be placed in a chamber at a temperature  $T$ , and the balancing electromotive force be reduced infinitesimally, so that a quantity  $e$  of electricity passes reversibly through the cell. The electrical work done is  $Ee$ . In the indicator diagram,

Fig. 107.

Fig. 107, we travel along the isothermal line  $AB$ , and the cell absorbs a quantity  $h$  of heat to keep its temperature constant.

Let us suppose that the system is thermally isolated, and that a further infinitesimal electric transfer occurs in the positive direction. The cell will either heat or cool; let us suppose that it cools to a temperature  $T - \delta T$ . If its electromotive force be continually balanced, the process will be reversible. Now let us place the system in an isothermal chamber at a temperature  $T - \delta T$ , and make the balancing electromotive force infinitesimally greater than that of the cell. An electric current flows in the negative direction, and the chemical changes of the cell are reversed. The indicating point in the diagram passes from  $C$  to  $D$ , and a certain amount of electrical work is done on the cell. If, then, the system be thermally isolated, a further infinitesimal negative electric transfer will heat the cell reversibly to its original temperature  $T$ .

Now, if  $\delta T$  is a very small temperature interval, the area of the figure  $ABCD$  in the indicator diagram—the area which gives

the balance of electrical work done by the cell during the cycle—is independent of the particular shape of the ends, and is measured by the product of the length of the figure and its breadth. Whatever exact reversible operations are needed to take the cell from one isothermal line to the other, the electrical work is therefore given by the product of the length and breadth of the figure. The length is  $e$ —the total electric transfer through the cell during either isothermal process—and the breadth is given by the difference in the electromotive forces at the two temperatures. This difference  $\delta E$  is clearly measured by the product of the temperature difference  $\delta T$  and the rate of change  $dE/dT$  of electromotive force with temperature. Hence the useful electrical work gained from the cell during the cycle, or the area of the figure  $ABCD$ , is

$$e\delta E = e\delta T \frac{dE}{dT}.$$

By the well-known expression for the efficiency of a reversible heat-engine, the ratio of the external work done to the heat  $h$  absorbed from the source during the hotter isothermal operation is equal to the ratio of the temperature range over which the engine works to the absolute temperature of the source. Thus

$$\frac{e\delta T \frac{dE}{dT}}{h} = \frac{\delta T}{T},$$

and

$$h = eT \frac{dE}{dT}.$$

This equation gives us the value of the reversible heat absorbed by the cell during the isothermal production of a current; that is, the heat which must be supplied at a temperature  $T$  in order to prevent the temperature changing when an amount  $e$  of electricity passes through the cell in the direction of its own electromotive force. If the temperature coefficient of the electromotive force be positive, that is, if the electromotive force of the cell increase with increasing temperature,  $h$  is positive also, and heat must be taken into the cell to keep it isothermal. Left to itself, then, such a cell will cool when giving a current. On the other hand, if  $dE/dT$  be negative, the cell will be heated by an electric transfer. Both

these effects are, of course, independent of the non-reversible Joule effect, by which an amount of heat  $C^2Rt$  is developed by the passage of a current. If the current be made very small, the Joule effect may be neglected compared with the reversible effect.

The analogy of this reversible effect with that discovered by Peltier at the junction of two different metals (§ 49) is manifest, and suggests that the site of the present phenomenon is to be sought at the interfaces between the electrodes of the cell and the liquids contained therein. This conclusion has been verified experimentally by Jahn and by Gill, who find the local thermal effects are in accordance with theory.

When a reversible voltaic cell is giving a current, the source of the energy is clearly the chemical action. If the same amount of chemical action were to take place in a calorimeter, without the performance of external work, the system might be brought to the same final state, with the same internal energy. In this case, all the energy goes into heat, and the calorimetric heat  $H$  evolved is a measure of the change in internal energy. When used to drive a current, the same decrease in internal energy must supply the electrical energy  $Ee$ , and also any reversible heat evolved at the junction in the circuit. "Heat evolved" means heat leaving the system, and thermodynamically is to be reckoned negative. But, as we have seen, the reversible heat  $h$  is equal to  $eTdE/dT$ . Hence we have

$$H = Ee - eT \frac{dE}{dT}.$$

If  $\lambda$  denote the calorimetric heat evolved by an amount of chemical action corresponding with unit electric transfer,  $H$  may be replaced by  $\lambda e$ , and we obtain the relation

$$\lambda = E - T \frac{dE}{dT},$$

or

$$E = \lambda + T \frac{dE}{dT},$$

an expression for the electromotive force of a voltaic cell, which was obtained by von Helmholtz, and, in a different way, by Willard Gibbs.

This equation is a particular example of the general equation connecting the change in the internal energy of a system with what is known as the free or available energy. The available energy  $A$  is the amount of external work obtainable by an infinitesimal, isothermal, reversible change in the system—in the case considered, obviously the electromotive force  $E$  multiplied by the electric transfer  $e$ . The change  $I$  in the internal energy is  $\lambda e$ , and we may write our equation in the general form

$$A = I + T \frac{dA}{dT},$$

which is applicable to any reversible physical or chemical system.

Returning to the consideration of the equation for the electromotive force, it will be noticed that, if  $dE/dT$  be zero, the electromotive force is measured by the heat of reaction per unit electrochemical change. The earliest formulation of the subject, due to Lord Kelvin, assumed that this relation was true in all cases; as, calculated in this way, the electromotive force of Daniell's cell, which happens to possess a very small temperature coefficient, agreed with observation.

When one gramme of zinc is dissolved in sulphuric acid, 1670 thermal units are evolved. Hence for the electrochemical unit, or 0.003388 gramme, the thermal evolution is 5.66 calories. Similarly, the calorimetric heat corresponding to the electrochemical unit of copper is 3.00 calories. Hence, the thermal equivalent of the unit of electro-chemical change in Daniell's cell is 2.66 calories. The dynamical equivalent of the calorie is  $4.18 \times 10^7$  ergs, and the electromotive force should be  $1.112 \times 10^8$  c.g.s. units or 1.112 volts—a close agreement with the experimental result of about 1.08 volts.

For cells in which the electromotive force changes with temperature, the accuracy of the equation of Helmholtz and Gibbs has also been confirmed experimentally.

**89.** As stated above, an electromotive force is produced whenever there is a difference of any kind at two electrodes immersed in electrolytes. In ordinary cells

Concentration  
cells.

the difference is secured by using two dissimilar metals, but an electromotive force exists if two plates of the same metal are placed in solutions of different substances, or of the same substance at different concentrations. Another method is to use in the same solution electrodes of different concentration. Such electrodes can be constructed by taking hydrogen in contact with platinized platinum, and making the pressure different at the two ends. In all such cells the electrical energy is not obtained from chemical changes, but from the energy of expansion of substances from greater to smaller concentrations.

Let us take as an example of a concentration cell the arrangement

silver / dilute silver nitrate / concentrated silver nitrate / silver.  
Here metal dissolves in the more dilute solution, and is deposited from the more concentrated solution, and this process will continue, since it involves a decrease of available energy, till the concentrations are equalized.

When one electrochemical unit of electricity passes, one gramme-equivalent of silver dissolves at the anode, and an equal quantity is deposited at the cathode. In this manner, the anode vessel must gain one gramme-equivalent of salt and the cathode vessel lose the same amount. Now let us consider the motion of the ions through the solution. The current, which is exclusively carried by silver ions at the electrodes, is shared between silver ions and  $\text{NO}_3$  ions in the body of the liquid. If the ionic velocities were the same, therefore, half a gramme-equivalent of each ion would pass across the surface of contact of the solutions. In the general case, when the transport ratio of the anion is  $r$ , and that of the cation  $1 - r$ , the anode vessel will, on the whole, gain  $1 - (1 - r)$  or  $r$  gramme-equivalents of silver and therefore of salt, while the cathode vessel must lose an equal amount, the difference between this case and that considered on p. 233 consisting in the fact that now we have a dissolvable anode.

In order to apply thermodynamical reasoning to this case, and so obtain an expression for the electromotive force, we must, in some way, complete the cycle of operations, and undo the changes which have occurred in the cell; we must re-concentrate the solution which has lost salt, and re-dilute the one which has gained

salt. This process may be performed in one of two ways. We may evaporate solvent from the one solution, and re-condense it again on to the other, or we may effect the same result by what is called an osmotic process.

As we shall see later (§ 96), when confined in a cell permeable to solvent but not to solution, a dissolved substance sets up, by the entrance of solvent, a certain pressure called the osmotic pressure. Both theoretically, as a consequence of thermodynamics, and practically, by experiment in cases such as sugar solutions, the osmotic pressure has been shown to be equivalent to the pressure exerted by a gas which, per unit volume, contains the same number of molecules as the solution contains molecules of solute.

Let us return to the consideration of our concentration cell. By the electrical process, which involves unit electric transfer through the cell,  $r$  equivalents of salt have been transferred from the concentrated to the dilute solution. It remains to describe some process by means of which we may imagine the  $r$  equivalents of salt returned from the dilute to the concentrated solution.

Let us place the more dilute solution, which has received additional salt by reason of the electric transfer, in an engine-cylinder, of which the bottom is pervious to the solvent but not to the salt, and is backed by a large volume of the pure solvent. Let the pressure on the piston be that of equilibrium. Allow this pressure to fall by an infinitesimal amount, so that solvent enters the solution till the concentration is again exactly as it was before the electric transfer. The change in concentration is very small if a large volume of solution be present, so that the process practically occurs at constant pressure and the work gained is  $P_1 v_1$ , where  $v_1$  denotes the change in volume, and  $P_1$  the constant osmotic pressure. Now separate bodily from the solution that volume of it which contains the amount of salt transferred by the current, and reversibly compress this quantity in an osmotic cylinder till its osmotic pressure rises to  $P_2$ , that of the more concentrated solution of the cell. The work done by the osmotic forces is  $-\int_{P_1}^{P_2} P dv$ . Finally place this liquid in contact with the stronger cell solution, connect it through a semi-permeable wall with the reservoir of the pure solvent, and squeeze out solvent

till the solution regains its initial volume by the expenditure of work equal to  $P_2v_2$ . The thermodynamic cycle is then complete.

Since both the electrical and the osmotic processes of this cycle can be made reversible and isothermal, the balance of external work must vanish. Denoting the electromotive force by  $E$ , and considering the electric transfer  $e$ , we may write

$$Ee + P_1v_1 - \int_{P_1}^{P_2} Pdv - P_2v_2 = 0.$$

If we restrict ourselves to dilute solutions, for which the gaseous laws hold good,  $P_1v_1$  must be equal to  $P_2v_2$  and we have

$$Ee = \int_{P_1}^{P_2} Pdv.$$

Now, as we shall see later, the osmotic pressure of dilute solutions of electrolytes has a value such that, on the gaseous laws, we must suppose that each ion of the salt produces its own pressure effect. If  $n$  be the number of ions given by one molecule of the salt, the pressure will, in very dilute solutions, be greater than that of an equivalent solution of a non-electrolyte in the ratio of  $n$  to 1.

Again,  $e$  is the electric transfer needed to liberate one gramme-atom of two opposite monovalent ions at the electrodes, and therefore to decompose one gramme-molecule of a monovalent salt. If the salt does not yield two opposite monovalent ions, let  $y$  be the total valency of the anions or of the cations obtained from one molecule; for instance,  $y$  will be 2, whether the cations be two monovalent ions such as the two  $H'$  + ions of a molecule of sulphuric acid, or one divalent ion such as the  $Cu''$  + of copper sulphate. The total electric transfer corresponding with the decomposition of one gramme-molecule of salt, and the liberation of one gramme-atom of each of the ions, is  $ey$ .

For dilute solutions, the usual gaseous laws apply, and, with non-electrolytes, we may write the equation

$$Pv = RT,$$

where  $v$  is the volume occupied by one gramme-molecule of the

solute,  $T$  is the absolute temperature, and  $R$  is a constant. Keeping the same meaning for  $T$ ,  $R$ , and  $v$ , in the case of dilute electrolytes, the pressure is greater in the ratio of  $n$  to 1, where  $n$  is the number of ions given by one molecule of the electrolyte. We then have

$$P = \frac{nRT}{v}.$$

In the concentration cell we have described, instead of one gramme-molecule, we have to deal with a transfer of  $r$  gramme-molecules, and we must write

$$P = \frac{nrRT}{v}.$$

The equation between the electrical and the osmotic work, namely,

$$Eey = \int_{P_1}^{P_2} Pdv,$$

now becomes

$$\begin{aligned} E &= \frac{nrRT}{ey} \int_{v_1}^{v_2} \frac{1}{v} dv \\ &= \frac{nrRT}{ey} \log_e \frac{v_2}{v_1} \\ &= \frac{nrRT}{ey} \log_e \frac{P_1}{P_2}. \end{aligned}$$

In dilute solutions, the osmotic pressures are proportional to the concentrations  $C_1$  and  $C_2$ . Hence we obtain, as an expression for the electromotive force of our concentration cell,

$$E = \frac{nrRT}{ey} \log_e \frac{C_1}{C_2}.$$

The numerical value of this expression may be calculated. For decinormal and centinormal solutions of silver nitrate, the transport number  $r$  is the same, and is equal to 0.528. In a cell containing these liquids, at a temperature of 18° C. or 291 absolute,

$$E = \frac{2 \times 0.528 \times 8.28 \times 10^7 \times 291}{9653 \times 1} \times 2.303 \times \log_{10} 10$$

since  $R$ , the gas constant per gramme-molecule, has the value  $8.28 \times 10^7$ . Hence

$$\begin{aligned} E &= 0.060 \times 10^8 \text{ c.g.s. units,} \\ &= 0.060 \text{ volts.} \end{aligned}$$

Nernst measured the electromotive force of this cell experimentally, and found the value

$$E = 0.055 \text{ volts.}$$

This number is in remarkable agreement with the result deduced theoretically. It confirms the general accuracy of the thermodynamic treatment of the subject given above, and shows that the assumption that solutions may be treated as "dilute" is justified for this purpose at the concentrations chosen.

The concentration cell which we have taken hitherto as an example, namely

silver / dilute silver nitrate / concentrated silver nitrate / silver, depends on the migration number for the anion. Cells have also been devised in which the electromotive force depends on the migration number for the cation, and other cells in which the effects of migration are altogether eliminated. An equally good agreement between theory and observation is found in these cases also.

The logarithmic formulæ for all these concentration cells indicate that theoretically their electromotive force can be increased to any extent by diminishing without limit the concentration of the more dilute solution;  $\log P_2/P_1$  then becomes very great. This condition can to some extent be realized in a manner that throws light on the general theory of the subject.

Let us consider the arrangement

Ag / AgCl with normal KCl /  $\text{KNO}_3$  / deci-normal  $\text{AgNO}_3$  / Ag.

The concentration of silver chloride is very small in saturated aqueous solution; from the electric conductivity it has been estimated as 0.0000117 normal. It is still further reduced by the presence of the large excess of chlorine ions of the potassium chloride.

The electromotive force of this cell has been calculated as 0.52 volt. This number was confirmed experimentally by Ostwald, who also examined other cells with similar electrodes giving high electromotive forces.

Hittorf has shown that the effect of a cyanide round a copper electrode is to combine with the copper ions. The concentration of the simple copper ions is then so much diminished that the copper plate becomes an anode with regard to zinc. Thus the cell

furnishes a current which carries copper into solution and deposits zinc. In a similar way silver could be made to act as anode in presence of cadmium.

**90.** The principles used in developing the theory of concentration cells show that the electromotive force of a  
Chemical  
cells. Daniell's cell will be raised by diminishing the concentration of the zinc sulphate solution, into which zinc dissolves, or by increasing the concentration of the copper sulphate solution, from which copper is precipitated. Compared with the total electromotive force, due chiefly to the chemical energy, these changes are of course small.

Similar ideas have been applied to the chemical changes themselves by Nernst and others, though in this case the basis of the investigation is more speculative. When a metal is placed in contact with the solution of one of its salts, and a current is passed across the junction and metal dissolved, changes occur in the chemical, osmotic, and electrical energies of the system. As the osmotic pressure of the solution rises, the tendency of the metal to dissolve as electrolytic ions becomes less, and it is suggested that eventually, at a certain pressure, no further tendency to dissolve would exist. Above this pressure the metal would tend to come out of solution and be deposited. This critical pressure bears no relation to the limit set to the osmotic pressure of a solution by reason of the finite solubility of the salt. With some metals it may be much too high to be reached, with others it may be too low. If the concentration of the solution giving the critical pressure could be obtained, so that there would be no

tendency for ions of the metal to enter or leave the liquid, it is fair to conclude that the metal and solution would be electrically neutral to each other, and that no difference of potential would exist between them. This critical osmotic pressure has been called the electrolytic solution pressure of the metal in the given solution. Nernst identifies it with the osmotic pressure of the ions of the metal in the substance of the metal itself. Such an idea is perhaps suggested by the osmotic pressure of certain metals when dissolved in mercury to form amalgams.

**91.** Any reversible cell can theoretically be employed as an accumulator; though, in practice, conditions of general convenience are more sought after than thermodynamic reversibility.

Secondary  
cells or ac-  
cumulators.

The accumulator commonly used can be made by placing two lead plates in dilute sulphuric acid, and passing a current between them. Hydrogen is evolved at the cathode, while the anode becomes covered with a layer of insoluble lead peroxide.

The cell is now in a condition to give a current in the reverse direction, during which process lead sulphate is formed at both electrodes until these become identical in constitution. In a second charging, the lead sulphate at the cathode is reduced to spongy lead, while at the anode it gives peroxide as before.

The mass of spongy material at the electrodes is increased by continual charging and discharging, a process which adds to the effective capacity of the cell; and the whole preliminary process of forming the cell can be hastened if the plates receive in the first place a coating of red lead,  $\text{Pb}_2\text{O}_3$ .

The main chemical action of a fully formed accumulator seems to be in accordance with the equation

which, read from left to right, describes the discharge, and, from right to left, the charging of the cell. Although ozone, hydrogen peroxide, persulphuric acid, and traces of lead persulphate have been detected, it seems likely that the above equation represents the chief part of the changes. The concentration of the acid solution is an important factor in determining the electromotive

force, which increases with increasing concentration, since part of the available energy of the reaction is due to the dilution of the residual acid by the water formed.

It is found in practice that the effective electromotive force of a secondary battery is less than that required to charge it; the energy efficiency of a lead accumulator is from 75 to 85 per cent., although from 94 to 97 per cent. of the current used in charging it can be regained. This drop in the electromotive force has led to the belief that thermodynamically the cell is only partly reversible. Dolezalek, however, has attributed the discrepancy to mechanical hindrances, which prevent the equalization of acid concentration in the neighbourhood of the electrodes, rather than to any essential irreversible chemical action.

On the provisional hypothesis that the system may be treated as reversible, the Gibbs-Helmholtz equation

$$E = \lambda + T \frac{dE}{dT}$$

has been applied. The discharge reaction for dilute solutions gives a calorimetric heat-evolution of 87,000 calories, which, on the assumption that the energy is all available, is equivalent to an electromotive force of about 1.88 volts. This number agrees with that observed for cells filled with weak acid, and indicates that the temperature coefficient is very small, a result which has been confirmed experimentally.

**92.** The source of the energy of a galvanic cell is certainly the chemical action, a correction being applied for any reversible heat which the cell absorbs from or gives up to its surroundings. The exact seat of the difference of potential, however, remained undetermined for a century, and proved a fruitful subject of discussion. Volta located it at the junction of the unlike metals; while Faraday's work, which showed the regular and fundamental part played by the chemical processes, seemed to indicate the surfaces at which the metals were in contact with the liquids. These two views of the nature of the phenomena have continued till the present, though it seems

Volta's  
contact effect.

that a considerable difference of potential probably exists at the surface of separation between metals and electrolytes or dielectrics such as air. The facts to be explained, besides those of the galvanic cell, are as follows.

Dry zinc and copper brought into contact with each other in dry air become oppositely charged, and, if their substances are arranged parallel and very close to each other, so as to form a condenser of large capacity, these charges may be considerable. They can be exhibited by separating the plates; the capacity is then diminished, and the difference of potential is thereby increased, so that it can be indicated by an electroscope or measured by an electrometer. The natural potential-difference produced by the contact of zinc and copper is about three-quarters of a volt.

Many experiments have been made on this subject. Ayrton and Perry have examined many metals, obtaining among others the following potential-differences in volts:

Zinc	}	0.210
Lead	}	0.069
Tin	}	0.313
Iron	}	0.146
Copper	}	0.238
Platinum	}	0.113
Carbon	}	

By the summation of potential-differences, a principle experimentally established by Volta, we can find the contact effect between any two metals in this list by adding together the values for all the pairs of intervening metals.

The theory of the cell given above suggests that the chief potential-difference is to be sought at the liquid-metal surface; but it is clear that, before any such interpretation can be accepted, it must be reconciled with the phenomena of contact electricity just described. On the analogy of the cell, the most natural explanation is that the contact potential-difference is due to the action of the oxygen of the air. It is not necessary to imagine actual oxidation; a sufficient cause might possibly be found in some slight modification of the film of condensed gas, which seems to exist on all solid surfaces, and to be so difficult to remove.

When, instead of the insulator air, the plates are surrounded by an electrolytic conductor, the slope of potential is accompanied by a current through the solution. At the contacts of the liquid with the metals, the natural potential difference is constantly tending to be set up again by the chemical affinity; thus a constant current is maintained, and zinc is actually dissolved.

The probability that the contact effect depends on the chemical action or affinity of the surrounding medium will be much increased if it can be shown that the magnitude of the effect depends on the nature of the medium. No change is produced by working in vessels at high exhaustion, or by placing the metals in an atmosphere of hydrogen. But the film of gas which clings to a solid is exceedingly difficult to remove, and it now seems likely that its persistence explains these negative results. From a research by Spiers, in which extraordinary precautions were taken to remove the film of gas, it is clear that the difficulties of getting rid of it have been greatly undervalued, and that, when it is really disturbed, large changes in the magnitude of the contact force are produced. Brown has shown lately that, if the copper and zinc plates are intensely heated in oil—a process which would remove the surface films—Volta's effect disappears. In such a case a few experiments that yield a positive result, and indicate a probable reason for the negative results of others, seem to carry great weight.

The phenomena of thermo-electricity have an intimate connexion with the subject now under consideration.

Let us consider a complete circuit of two metals,  $T_1$  and  $T_2$  being the temperatures of the junctions. Let  $\Pi_1$  and  $\Pi_2$  be the heat evolved by unit electric transfer at the junctions of the temperatures  $T_1$  and  $T_2$  respectively;  $\Pi_1$  and  $\Pi_2$  measure the Peltier effects. Let  $\sigma$  and  $\sigma'$  denote the coefficients of the Thomson effect in the two metals. In Chapter VI we showed that, considering unit electric transfer round the circuit, the energy principle leads to the result

$$E = \Pi_1 - \Pi_2 + \int_{T_1}^{T_2} (\sigma - \sigma') dT,$$

where  $E$  is the total electromotive force round the circuit, while the consideration of the entropy of the system gives us

$$\Pi = T \frac{dE}{dT}$$

for the Peltier effect at one junction.

Thus, while the Peltier effects depend on the temperature coefficient of the total electromotive force of the circuit, in the equation for  $E$  the Peltier effect appears as a local electromotive force at the junction. Each electric unit, as it passes across, introduces an energy effect  $e\Pi$ , which involves a reversible evolution or absorption of heat. The Peltier effects have been determined experimentally, and their electrical equivalents, which measure the contact potential-differences at the metallic junctions, are calculated as a few millivolts only, values much too small to explain by themselves the observed Volta effects, without taking account of similar effects at the surfaces of the surrounding dielectric.

93. Many attempts have been made to determine experimentally the single potential-differences at the

Single potential differences at the junctions of metals with electrolytes.

individual junctions in a circuit containing electrolytes as well as metals. In a galvanic cell, for

example, there must be at least two such junctions, and the problem is to separate their effects and measure the step of potential at each. The measured electromotive force gives the sum of all the single potential-differences, but the impossibility of connecting directly the electrolyte with an electrometer, without introducing another metallic junction, throws difficulties in the way of observing them individually. If a method could be devised capable of application to one such junction, the combination of that junction with any other would enable the value for the other to be calculated from the total electromotive force as observed in the usual manner.

It has usually been thought that the single potential difference at the common boundary of mercury and an electrolyte has been determined satisfactorily by experiments on capillary electrometers and by others in which mercury was allowed to drop into a solution from a fine glass nozzle.

Von Helmholtz pointed out that a potential difference at the junction of mercury with an electrolyte might be explained by the supposition of a double layer of electricity over the surface, the two opposing faces being oppositely charged—on the side of the electrolyte by the congregation of ions. Such a system would take time to reach its final state, and he concluded that, if mercury were allowed to drop rapidly from an orifice beneath the surface of a liquid electrolyte, the double layer would not be established, and the stock of falling mercury would be brought to the same potential as the electrolyte. The apparatus therefore might be used in connexion with an electrometer, the other quadrants being joined to a quantity of mercury at rest in the same electrolyte. A difference of potential of about 0·8 or 0·9 volt is obtained between the dropping mercury and the mercury at rest in dilute sulphuric acid, but there seems some doubt whether or not the dropping electrode is really at the potential of the electrolyte, and the trustworthiness of the method cannot yet be regarded as established.

Another method by which the measurement of single potential differences has been attempted depends on electro-capillary phenomena. The surface tension of the area of contact between the mercury and a solution is affected by its electrical state. If the surface be increased, an electric transfer is produced, and, conversely, if an external electromotive force be applied across the junction, the area tends to change, owing to an alteration in the effective surface tension. These phenomena have been applied by Lippmann to the construction of capillary electrometers, of which several forms are in frequent use. In one variety, a vertical glass tube is drawn to a very fine capillary. The tube is partially filled with mercury, and the lower portion immersed in an electrolyte,

Fig. 108.

usually dilute sulphuric acid, in which is placed another quantity of mercury. The capillary forces tend to raise the mercury surface in the little tube, and are balanced by the pressure of the long column. When the mercury in the vertical tube and the mercury below the electrolyte are connected with two conductors at different potentials, such as the opposite poles of a galvanic cell, a change is produced in the level of the surface of contact in the capillary tube. A microscope with a micrometer eyepiece may be arranged to view the capillary, and, for small differences, the change in level is found to be proportional to the applied difference of potential. The movement is slow, and the final position of the meniscus is not reached for an appreciable time, probably owing to the high values of the electrical resistance of the column of electrolyte in the capillary, and of the frictional resistance to the movement of liquid through such a narrow tube. While the applied electromotive force is a small fraction of a volt, the electrometer behaves as a condenser of good insulation, retaining its charge for several hours when disconnected from the cell. On the other hand, when the applied voltage is greater, electrolysis at the surface seems to occur, and the charges leak away.

An explanation of these phenomena, based on Lippmann's observations, has been given by von Helmholtz, on the assumption that no electrolysis occurs. Any natural potential difference between two bodies implies an electrification over the boundary, in such a manner that an electric condenser of minute thickness is formed, with its parallel faces oppositely charged. This electric double layer will produce an electrostatic surface energy  $\epsilon$ , the value of which is  $\frac{1}{2}CAV^2$ , where  $C$  is the capacity of the double layer per unit surface,  $A$  the area of contact, and  $V$  the potential difference across the layer. Now if  $V$  be kept constant, and the area be increased, we have for  $d\epsilon/dA$  the value  $\frac{1}{2}CV^2$ . This increase in available energy is obtained from the chemical energy which maintains the natural potential difference, just as the increase of energy in the quadrant electrometer described on page 46 is obtained from the battery. In that case, the needle tends to move so as to cover more of the oppositely charged quadrants; and here the area of the double layer, that is, the area of contact between mercury and electrolyte, tends to increase. This effect

therefore acts in a sense opposite to that of the ordinary surface tension  $S_0$ . The resultant surface tension  $S$  will be

$$S = S_0 - \frac{1}{2}CV^2.$$

On the assumption that the only effect of the potential difference is to produce such an electrostatic effect,  $S_0$  will be independent of  $V$ , and the total observed surface tension will reach a maximum when  $V$  is zero.

Lippmann and others have found that, in agreement with the equation given above, the curves drawn between the external electromotive force and the reading of a capillary electrometer rise to a maximum and then fall again, their form being roughly parabolic; with dilute sulphuric acid, the maximum of the curve is reached when about one volt is applied.

By using liquid amalgams, the same electrolyte can be compared with mercury and what is effectively a different metal. Rothmund and others have compared the difference of the values thus measured with the electromotive force of the cell

amalgam / electrolyte / mercury,

finding concordant results.

The results of these experiments on the whole favour the view that the electromotive force of a cell is approximately the sum of the single potential differences at its electrodes as determined by the capillary electrometer. On the other hand, there is evidence to show that, in general, the result of an applied electromotive force on the surface tension is not merely the electrostatic effect contemplated by the Helmholtz theory, but that it depends also on the chemical nature of the electrolyte. Whichever side of the electric double layer is positive, its effect is opposite to that of the natural surface energy, but there is no reason to suppose that the effect of anions and cations on the electrolyte side of the double layer will be identical. The total electrocapillary curve therefore probably consists of parts of two parabolas which meet at a point, and a slight want of symmetry observed in the ascending and descending branches of the experimental curves is thus explained. Van Laar, who has considered this effect in detail, concludes that

single potential differences cannot be determined accurately by means of the capillary electrometer.

It is evident from what has been said that there is some doubt whether the experiments on dropping electrodes and on capillary electrometers really enable us to calculate even approximately the natural potential difference which is involved in the electromotive force of a galvanic cell containing a mercury-electrolyte surface. Nevertheless, since many useful determinations of other single potential differences, which, at all events, are relatively exact, rest on such measurements, in the present condition of the subject we may provisionally accept the value of about  $+0.92$  volt as the potential difference between mercury and dilute sulphuric acid, the mercury being positive to the acid. The step of potential as thus measured is in the opposite direction to that which occurs at the surface of a zinc plate. Results are obtained for other metal-electrolyte surfaces by subtracting this number, or another similarly estimated for mercury in contact with some other electrolyte, from the total electromotive force of galvanic cells arranged in the manner

metal / electrolyte / mercury.

Such indirect determinations will contain as a constant error any deviation of the primary measurement from the true value, but, as relative numbers, serving to compare the metals among themselves, they will retain their importance.

In making such experiments, it is usual to employ what is known as a normal electrode, consisting of a quantity of pure mercury covered by a layer of mercurous chloride and a solution of potassium chloride of normal concentration, that is, a solution containing one gramme-equivalent per litre. An indiarubber tube ending in a glass tube leads from the solution and is filled with it (Fig. 109). Contact can thus be made between the potassium chloride and any other liquid. This electrode, as measured by Lippmann's method, gives a potential difference of  $0.56$  volt, the mercury tending to come out of solution and be deposited as metal. The chlorides can of course be replaced by other substances when their potential with respect to mercury is known. Thus a soluble sulphate, with mercurous sulphate as depolarizer, has been used.

Assuming that we may neglect the small effects at the junction of the metals, and at the surfaces of contact of unlike solutions, if such surfaces are present, the measured electromotive force of

Fig. 109.

the combination metal / electrolyte / normal electrode enables the potential difference at the surface metal / electrolyte to be calculated by subtraction.

In this manner, Neumann measured the single potential differences for many metals in contact with either normal or saturated solutions of their salts. The following are some of the most important results.

Metal	Sulphate	Chloride	Nitrate
Zinc	-0.524	-0.503	-0.473
Iron	-0.093	-0.087	-
Lead	-	+0.095	+0.115
Copper	+0.515	-	+0.615
Silver	+0.974	-	+1.055
Mercury	+0.980	-	+1.028

In this table positive signs have been assigned to those metals which show a positive potential relatively to the liquids surrounding them. Assuming the accuracy of these results as absolute numbers, it follows that such metals tend to come out of solution, and the natural potential difference at their surfaces helps to drive a current in the direction to effect the deposition. Spontaneous separation of these metals, or solution of negative metals, however, will only occur if means be available for the simultaneous

addition of opposite ions, or the removal of an equivalent quantity of similar ions.

For slightly oxidizable metals, such as silver, it will be seen that the method leads to numbers which have a sign opposite to that assigned to the values for very oxidizable substances such as zinc.

If we regard the potential differences as due to the potential energy of possible chemical changes, such a difference in sign seems, at first sight, unexpected. Moreover, in correlating these phenomena with those of the Volta contact effect between metals in air, it is probable that there will at all events be a general agreement between them, and it seems unlikely that metals would show a difference of sign in their potential differences with air, if that difference is due to actual oxidation, or to an affinity which tends to oxidation. On the other hand, Nernst's theory of electrolytic solution pressure offers a possible explanation of the difference in sign as given above. Whatever be the final outcome of the problem, we may take Neumann's numbers and similar results as true relative values, though eventually a constant error may have to be added to or subtracted from them.

The deposition and solution of metals from solutions of their salts have been shown to be reversible processes, the slightest change of electromotive force being enough to reverse the operation. Hence Neumann's results give both the electromotive forces set up by the solution of such a metal as zinc, and the decomposition voltage needed to deposit it from a solution of the same concentration.

The potential-differences rise with the dilution of the solution, and it seems not unlikely that some approximation to the logarithmic formulæ of concentration cells may hold also in the present case. If so, the potential-difference would assume a very high value for a very dilute solution.

Electrolysis has long been used to separate metals from each other. The theory of this process will now be clear. Let us suppose that we have a mixed solution of zinc and copper

sulphates. The deposition point of copper is  $-0.515$  volt, and that of zinc  $+0.524$  volt. Thus, if the total electromotive force applied be enough to give a potential difference at the cathode greater than  $-0.515$  volt but less than  $+0.524$  volt, copper only will be deposited, for although its deposition point rises as the amount of copper gets less, this change is very small, and all traces of copper which could be detected by chemical analysis will be removed from the solution before the deposition point rises to that of zinc. If the electromotive force at the cathode be now increased above  $+0.524$  volt, the zinc likewise can be removed from solution.

Even without this adjustment of electromotive force, if the solution be kept well stirred to prevent the local exhaustion of one metal at the electrodes, complete separation can nearly be effected. For, as we have seen, as long as there is any of the metal of lower deposition point present, none of the other is liberated. This principle is used in a process of copper refining. A plate of pure copper forms the cathode in a bath of copper sulphate. The anode is a thick plate of impure copper, probably containing metals both less and more easily deposited than copper. The bath is stirred, and when the current flows, copper and all more oxidizable metals are dissolved, while the less oxidizable metals, such as gold and silver, fall to the bottom of the vessel; for while copper is present in excess the current will dissolve it rather than more resisting metals. In the neighbourhood of the cathode, however, there will be a large excess of copper together with other metals, such as zinc, more easily oxidizable and therefore of higher deposition points. As long as any copper is near, therefore, none of the other metals are deposited, and pure copper is obtained at the cathode.

On the other hand, by increasing the current density, it is usually possible to exhaust the one metal from the layers of solution next the electrode faster than either stirring or diffusion will replace it. The other metal must then also be used by the current, and, by proper adjustment of conditions, it is possible to deposit alloys, the percentage composition of which can be altered by varying the current density.

94. Another set of electrocapillary phenomena, like those considered above, probably depend on the natural potential differences at the surface of separation of two unlike substances—in this case an electrolyte and an insulator. If an electric current be passed through a vessel divided into two compartments by means of a porous partition and filled with some solution, we shall find that, in general, besides the changes in concentration at the electrodes which were described on p. 233 under the head of migration, there is a bodily transfer of the liquid, usually in the direction of the current, through the porous plate. To this phenomenon the name of electric endosmose is given.

If the pressure be kept constant on both sides of the partition, the volume of liquid which flows through, as measured by the overflow, is proportional to the total electric transfer, and is independent of the area and thickness of the plate; it varies much with the nature of the solution, being greater with liquids of high specific resistance, and, in solutions of different concentrations of any one substance, is approximately proportional to the specific resistance.

If the liquid be not allowed to overflow, the pressure on one side of the porous wall will increase. The final pressure is directly proportional to the electromotive force between the faces of the partition, and therefore to the current through it; for a given current it varies inversely as the area of face of the porous wall and directly as its thickness. In this case, the flux of liquid due to the electric forces must be equal and in the opposite direction to that caused by the difference of hydrostatic pressure. Considering the porous wall to consist of a collection of capillary tubes, we may apply the laws of flow through such tubes to the reverse flux under the hydrostatic forces, and this explanation has been supported by Quincke, who proved that the pressure produced by electric endosmose through a capillary glass tube was inversely proportional to the fourth power of the diameter of the tube. The pressures were considerable with distilled water, but ceased to be perceptible with liquids of high conductivity such as solutions of salts and acids.

95. Throughout our investigation of the electrical properties of solutions we have constantly been led to infer that the ions of electrolytes are to a certain extent independent of each other. If we eliminate the polarization at the electrodes, the flow of the current is in accordance with Ohm's law, and therefore, any electromotive force, however small, will produce a corresponding current. Hence there can be no appreciable reverse electric forces to be overcome in the interior of the electrolyte. The applied electromotive force, then, simply moves the ions against the frictional resistance of the liquid, it does no work in separating them from each other. We see that the electric properties of solutions indicate a freedom of interchange between the parts of the dissolved molecules—a freedom also suggested by the phenomena of chemical double decomposition.

The existence of specific coefficients of mobility, as characteristic properties of certain ions in very dilute solutions, involves the idea of independent migration, and suggests that the freedom of the ions from each other persists during the greater part of the time, and is not merely a power of interchange at the moments of molecular collision. If it were only a momentary freedom, the convective passage of the ions in opposite directions through the liquid, indicated by Faraday's law, would be explained by a continual handing on of the ions from molecule to molecule. The ions would work their way along by taking advantage of the intermolecular collisions, and the ionic velocities would depend on the frequency of these collisions; a frequency which, as indicated by the kinetic theory, depends on the square of the concentration. Now, as we saw on page 236, the conductivity of a solution varies as the product of the concentration and the relative ionic velocity; on this view, then, the conductivity will be proportional to the cube of the concentration. The facts described on page 231 do not bear out this result. In dilute solutions in water at all events, the conductivity is proportional to the concentration, and, as the concentration rises, the conductivity increases at a slower rate. It is difficult to see how these relations could hold except as a consequence of an almost complete migratory freedom of the

The theory  
of electrolytic  
dissociation.

ions of dilute aqueous solutions, and very strong evidence is thus obtained in favour of a theory of ionic dissociation.

Preconceived ideas would not, perhaps, lead us to expect that substances, which, like the mineral salts and acids, show great chemical stability when solid, should be dissociated into their ions almost completely when dissolved in water. It must, however, be remembered that it is precisely these bodies which possess the greatest chemical activity, that is to say, most readily exchange their parts with those of other substances. That a solution of hydrochloric acid, again, does not exhibit the properties of dissolved hydrogen and chlorine, though it has been urged as an objection, is not a valid argument against the theory of dissociation, for the ions are certainly in conditions differing from those in which the atoms of the same elements exist in their usual state. Whether or not there is combination between the ions and the solvent, and whatever be the exact relation between the ions and the charges they carry, we are certain that a definite quantity of electricity has to pass between an ion and the electrode before the substance can be liberated in a normal chemical state, say as gaseous hydrogen or chlorine. The energy associated with a substance when ionized must therefore be very different in quantity and character from that associated with it when in its normal chemical condition, and there is no reason to assume identity of properties in the two states.

It has been suggested that, if really dissociated from each other, the two ions of a dissolved salt would generally diffuse at different rates, and therefore ought to be separable. If such separation occurred to any large extent, however, electrostatic forces between the ions would arise and increase till further division was prevented. Nevertheless, some separation should undoubtedly occur, and, as a matter of fact, a volume of water in contact with the solution of an electrolyte is found to take, relatively to the solution, a potential of the same sign as the charge on the ion which has the greater mobility and therefore the quicker rate of diffusion.

The rate of diffusion may be calculated by treating the osmotic pressure as the driving pressure, and reckoning the speed attained

from the known mobilities of the ions under electrical forces. The values of the diffusive constants and potential-differences thus deduced agree well with those found by experiment.

The dissociation required by the theory is a separation of the ions from each other, securing complete migratory independence. There is nothing to suggest that the ions are free from all chemical combination. The hypothesis of electrolytic dissociation is entirely independent of any particular view as to the nature of solution, which may well be chemical in its fundamental processes. All that is required to interpret the electrical phenomena is the freedom of the migrating ions from each other; they may quite possibly be combined in some way with the solvent.

In some cases, particularly in solvents other than water, it seems necessary to assume that the solute exists in solution as double or treble molecules, which, by dissociation, give rise to electrified ions. We may, on the other hand, have double molecules formed between one molecule of the salt and one or more of the solvent, structures such as  $\text{NaCl} \cdot 2\text{H}_2\text{O}$ , which then dissociate into  $\text{Na}^+ \cdot \text{H}_2\text{O}$  and  $\text{Cl}^- \cdot \text{H}_2\text{O}$ . Evidence is now accumulating, however, which seems to show that the ions of electrolytic solutions are to be imagined as composed of a central charged nucleus (the Na or Cl in the case taken) round which are collected numbers of solvent molecules, forming an inclosing envelope which moves with the nucleus, and forms an essential part of the ion. The size of this structure may depend on the temperature and the other conditions of the solution.

Such hypotheses as to the nature of the ions do not affect the main conception of the dissociation theory, which holds that the parts of the electrolyte (the Na and Cl in our example) are independently mobile in the solution. So much seems to be demanded by the electrical evidence, and by certain osmotic phenomena which we must now describe.

**96.** Certain membranes, made by depositing insoluble chemical precipitates within the walls of porous earthenware cells, are found to be permeable to solvents, and impermeable, or much less permeable, to certain substances when dissolved therein. In a closed cell with such a semipermeable wall,

Osmotic  
pressure.

the presence of a solution will cause solvent to enter from without, and a pressure will be set up within, which finally reaches an equilibrium value known as the osmotic pressure of the final solution.

Whatever view we take of the fundamental nature of a solution, we must imagine the dissolved substance scattered as a number of discrete particles throughout the volume of the solvent. The nature of the interaction which occurs between the solute and the solvent is unknown, possibly unknowable ; but, whatever it may be, each particle of solute will affect only a minute sphere of solvent lying round it. The solution, then, may be regarded as containing a number of little systems, each composed of a solute particle surrounded by an atmosphere of solvent in some way influenced by its nucleus.

While the solution is concentrated, the little spheres will intersect each other, and the addition of further solvent will involve some change in the interaction between solute and solvent. But, in the process of dilution, a time will come when the spheres are beyond each other's reach, and the addition of more solvent merely increases their mutual separation without affecting their internal structure.

Thus, in a dilute solution, the energy-change of further dilution is merely the energy-change involved in separating the particles of the solute further from each other ; it will not depend on the nature of any possible interaction between the solute and the solvent. The change of energy is thus independent of the nature of the solvent, and will be the same whether that solvent be water, alcohol, or any other liquid. It will even be the same when, in cases where that is possible, the solvent is removed altogether, and the solute is obtained in the gaseous state.

If we imagine that the bottom of a frictionless engine cylinder is made of a semipermeable membrane, separating a solution within the cylinder from a solvent without, it is easy to see that osmotic pressure may be made to do work, which will be measured by the pressure multiplied by the change of volume. Thus the osmotic pressure is measured by the change of the available energy per unit increase of volume ; that is, by the rate of change with volume in the available energy of dilution.

In this manner we arrive at the conclusion that the osmotic

pressure must be equal in amount to the gaseous pressure exerted by the same number of molecules when vaporised, and must conform to the laws which describe the temperature, pressure, and volume relations of gaseous matter. The result is seen clearly to be independent of any hypothesis concerning the mechanism of the pressure or the nature of the solution.

By the principles of thermodynamics, a connexion may be traced between the osmotic pressure of a solution and the difference between the freezing and boiling points of the solution and of its pure solvent. Thus, the number of pressure-producing particles in a given solution may be determined by measuring its osmotic pressure, the depression of its freezing point, or the rise of its boiling point compared with those of the solvent.

In certain dilute solutions, such as those of sugar in water, the gaseous value for the osmotic pressure has been verified by direct measurement. This is confirmed also by observations on the freezing points, and, in this case, it is easy to extend the experiments to solutions of electrolytes which appear to leak through semipermeable membranes. The freezing points of very dilute aqueous solutions of electrolytes indicate a number of pressure-producing particles greater than that suggested by the ordinary molecular weight of the salt, and, for the most dilute solutions examined, greater in the approximate ratio of the number of ions into which the salt must be imagined to be dissociated in order to explain the electrical relations.

Thus, in dilute aqueous solutions the evidence goes to show that certain solutes are dissociated, and that the dissociation is the same in kind as that required to explain the electrical phenomena. In other solvents dissociation into non-electrified parts seems sometimes to occur, for cases are known where the osmotic effects indicate dissociation, but no electrical conductivity exists. For solutions in water, however, the same kind of dissociation is indicated by the two lines of research. It is, perhaps, advisable to repeat that the dissociation needed is the separation of the ions from each other, not necessarily from the solvent; the dissociated ions may well be linked with solvent molecules, or act as nuclei at the centres of watery envelopes as already suggested.

97. A relation has been traced between the coefficients of chemical affinity of solutions of acids and bases and their electrical conductivity. It seems likely that, in dilute aqueous solution, the electrical ions of the solute alone are concerned in quick chemical interchanges, though here, again, rapid changes seem to occur in other solvents with solutions which show no conductivity.

If dilute solutions of acids and alkalies are to be regarded as containing only dissociated ions, the process of neutralization of hydrochloric acid and potash will be represented by the equation

The resultant water, in presence of an excess of its own substance, is dissociated only to a very slight extent, and we see at once the explanation of the observed fact that equivalent quantities of all strong acids and alkalies evolve the same amount of heat when reacting with each other: the only chemical change consists in the formation of a molecule of water from its ions, and this holds whatever be the acid and alkali, provided they are highly dissociated.

If we assume that the solution of an electrolyte is so dilute that the solute particles and their attendant watery atmospheres are beyond each other's influence, the number of molecules dissociating into their ions per second will be proportional to the concentration  $c_1$  of the undissociated molecules. Two ions will recombine in a certain fractional number of the cases of collision between two opposite ions. The number of recombinations per second will therefore be proportional to the product of  $c_2$  the concentration of one ion and  $c_3$  that of the other. These concentrations are equal, and the rate of recombinations varies as  $c_2^2$ .

When equilibrium is reached, the rates of dissociation and recombination will be equal, and we have

$$k_1 c_1 = k_2 c_2^2.$$

If  $\alpha$  be the coefficient of ionization, and  $v$  the volume of the solution containing one gramme molecule of solute,  $c_1$  will be  $(1 - \alpha) v$ , and  $c_2$  will be  $\alpha/v$ . Hence

$$\frac{\alpha^2}{v(1 - \alpha)} = \frac{k_2}{k_1} = \text{constant}.$$

This result, known as Oswald's dilution law, is true for weak electrolytes such as ammonia or acetic acid, but fails for strong electrolytes such as potassium chloride or hydrochloric acid. Probably the extended influence of charged ions, compared with that of neutral molecules, causes the attendant watery atmospheres of ions to be so large that the solutions cease to be effectively "dilute" even at very small concentrations.

**98.** Colloidal substances, such as hydrated alumina, travel through liquids when their solutions are subjected to an electromotive force, the direction of motion depending on the nature of the solvent. This result indicates that the colloid particles possess electric charges. Such solutions are coagulated by the addition of an electrolyte, and the coagulative powers of different electrolytes depend, in a very remarkable way, on the chemical valency of the ion with opposite charge to that on the colloid particles. The average of the coagulative powers of salts of univalent, divalent, and trivalent metals are found to be proportional to the numbers 1 : 35 : 1023 respectively. An explanation of these phenomena has been offered by the present writer.

Let us suppose that, in order to produce the aggregation of colloidal particles which constitute coagulation, a certain minimum electric charge has to be brought within reach of a colloidal group, and that such conjunctions must occur with a certain minimum frequency throughout the solution. Since the electric charge on an ion is proportional to the valency of the ion, we shall get equal charges by the conjunction of  $2n$  triads,  $3n$  diads, or  $6n$  monads, where  $n$  is any whole number.

The chance conjunctions of a large number of particles moving like the ions of an electrolytic solution can be investigated by the principles of the kinetic theory of gases. If  $1/x$  denote the chance of one ion colliding with a colloidal particle, the chance that two ions should collide with it is the product of their separate chances, or  $1/x^2$ , and so on. When applied to the case in hand, these principles lead to the conclusion that the relative coagulative powers of univalent, divalent, and trivalent ions will be proportional to the ratios  $1 : n : n^2$ . The value of  $n$ , which depends on a

number of unknown factors, remains arbitrary. If we assume that  $n$  is 32,  $n^2$  is 1024, and we get the numbers 1 : 32 : 1024 to compare with the experimental values of the relative coagulative powers 1 : 35 : 1023.

The fundamental principles of the theory of electrolytic dissociation are able to explain and coordinate many different groups of phenomena. To what extent the theory is applicable to solutions in solvents other than water, or to fused or solid electrolytes, is a problem now under investigation in many physical and chemical laboratories.

## CHAPTER XI.

### THE CONDUCTION OF ELECTRICITY THROUGH GASES.

Introduction. Electric discharge through gases at low pressure. Röntgen rays. Cathode rays. Ionization of gases. Conductivity of gases. Mobilities of gaseous ions. Ionization by collision. Gaseous ions as condensation nuclei. Diffusion of ions. The nature of gaseous ions. Ions from incandescent bodies. The corpuscular theory of conduction.

**99.** UNLIKE the liquid solutions and other electrolytes studied in the last chapter, gases, in normal conditions, are almost perfect insulators of electricity. Usually the leakage of charge from a body suspended in air is due mainly to a slight conduction along the supports. For a long time it was a subject of controversy whether or not any part of the leakage took place through the air. Although this question is now answered in the affirmative, the conductivity of gases is, in general, extremely small; it may, however, be increased greatly by the passage of Röntgen rays, the incidence of ultra-violet light on a metal plate, the neighbourhood of flames, of incandescent metals, or of radio-active substances.

Apparently the first to notice the electric spark was Otto von Guericke (1602—1686) of Magdeburg, the inventor of the air-pump. From his time forward the spark continued to excite the curiosity of investigators, and, as we have seen, Franklin proved its identity with the lightning flash.

By means of the spark, electrified bodies are discharged almost instantaneously, showing that a path of high conductivity is opened thereby. This fact is demonstrated in another striking manner by the phenomena of the electric arc, first described by Davy in 1801.

If the terminals of a battery of low resistance, giving 60 to 80 volts difference of potential, be connected with rods of hard gas carbon, an intensely luminous arc is started by touching the carbons and then drawing them a short distance apart. Automatic devices, which keep the carbons at a constant distance as their ends are consumed, are used in various kinds of arc lamps. The currents through arcs may rise to several amperes, and the conductivity is of the same order as that of metallic conductors. The phenomena of the spark and of the arc show that, in normal conditions, gases withstand a certain electric intensity, but that their resistance breaks down under a definite electric stress, and remains low if the current which then passes be maintained. This behaviour should be compared with that shown by metallic conductors conforming to Ohm's law; in their case the smallest electromotive force produces a corresponding current, which increases in direct proportion to the applied electromotive force. Again, in order to pass a current through an electrolytic solution, we must apply an electromotive force greater than the reverse force of polarization at the electrodes. But, in that case, the electromotive force needed to maintain the current is equal to that required to start it; the passage of the current does not modify the physical state of the medium.

**100.** The possible length of spark, with a given difference of potential, increases as the density of the gas is diminished by means of an air-pump. The relation between pressure and sparking potential was first investigated systematically in 1834 by Harris, whose experiments were confirmed and extended by Faraday in 1838. As exhaustion proceeds, the sparking potential diminishes, reaches a minimum, and then increases again very rapidly as the pressure sinks to a small fraction of a millimetre of mercury. In a "good vacuum," it is difficult to get any discharge to pass. The minimum sparking potential occurs at a pressure which depends on the length of spark-gap used. The critical pressure increases as the length of gap diminishes. Their product is very nearly constant; it is independent of the nature of the electrodes, and thus may be regarded as a characteristic property of the gas.

Electric  
discharge  
through gases  
at low  
pressure.

Since the critical pressure increases as the length of spark-gap diminishes, for very short spark-gaps the critical pressure is fairly high. Hence, at very low pressures, it is easier for a spark to pass by a long path through a gas than by a short one. This curious result shows that the passage of the spark is facilitated by the presence of more gas between the electrodes, in fact it has been found by Paschen and by Carr that the sparking potential depends only on the product of the pressure and the spark length—that is, upon the mass of gas between unit area of the electrodes.

Very beautiful appearances are presented by the discharge of an induction coil through gases at low pressure. The general type of discharge shows the following sequence of phenomena as the tube is exhausted. The first discharge consists of a luminous line down the middle of the tube. This line then broadens out till it seems to fill the tube. At pressures equivalent to that of about half a millimetre of mercury, a series of fluctuating striations, known as the positive column, appears in the neighbourhood of the

Fig. 110.

Fig. 111.

anode (*a*, Fig. 110). A narrow dark space, called Crookes' dark space, surrounds the cathode, and this is separated from a second

dark space, called after Faraday, by what is known as the negative glow.

By introducing platinum wires at different positions along the discharge, the distribution of potential has been investigated. Figure 111 shows a curve giving the relation between the distance from the anode and the potential-gradient in volts per centimetre. The difference of potential between the cathode and the negative glow is independent of the pressure of the gas or the distance between the electrodes. This potential-difference has been shown by R. J. Strutt to be equal to the minimum sparking potential.

If the length of the tube be increased, it is the positive column alone which increases with it; the two dark spaces, and the negative glow, vary very little with the length of the tube.

The effect of very high vacua on the electric discharge was first investigated systematically by Sir William Crookes. As the air is removed, it is found that the dark space nearest the cathode gradually extends, until eventually it fills the whole tube. At this stage, green phosphorescent effects begin to appear on the anode and on the glass opposite the cathode. If a solid object, such as a screen of mica, be interposed between the glass and the cathode, a sharp shadow is seen, showing from its position that rays capable of producing phosphorescence proceed in straight lines from the cathode. These cathode rays possess energy, for a light windmill placed in their path will rotate; moreover, they are deflected by a magnet, in the same direction as would be negatively electrified particles, travelling in the course of the rays. For this reason, Crookes and other English observers from the first contended that the cathode rays were to be regarded as a flight of negatively electrified material particles; while, on the contrary, it was believed for some time in Germany, where many experiments were also made, that the cathode rays, like those of ordinary light, were of the nature of æthereal waves.

**101.** In the year 1895, Professor Röntgen of Munich noticed that photographic plates became fogged, as though they had been exposed to light, if they were kept under cover in the neighbourhood of a highly exhausted tube through which electric discharges from an induction coil were passing. He

Röntgen rays.

investigated this effect, and found that, when cathode rays impinged either on the glass of the tube, or on the anode, or on any metallic plate within the tube, a type of radiation was produced which would penetrate many substances opaque to ordinary light. Dense bodies, like metal or bone, absorbed the rays more fully than did lighter materials, such as leather or flesh; and Röntgen, at once putting this discovery to some purpose, was able to photograph the coins in his purse and the bones in his hand. Moreover, Röntgen rays produce phosphorescence on screens of barium platino-cyanide and other similar salts, and, by using these screens in place of a photographic plate, objects, usually hidden from our eyes, may be made visible.

The form of apparatus usually employed for the production of Röntgen rays is shown in Fig. 112. The cathode is made of a

Fig. 112.

concave aluminium cup which focusses the cathode rays on to a second aluminium plate or anti-cathode, fixed near the middle of the exhausted bulb.

For several years after their discovery, the physical nature of the Röntgen rays was widely discussed, and for a long time no general consensus of opinion was reached. Their photographic effects and the fluorescence they produced on suitable screens suggested that, like ordinary light, they were to be regarded as waves in the luminiferous æther. The power they possess of penetrating some opaque substances does not forbid such an assumption, for a difference in the wave-length, that is, in the period of vibration, is sufficient to produce marked differences in the penetration of ordinary light. Glass, transparent to the visible rays, is opaque to those invisible rays of longer wave-length which possess great heating power—hence its use in fire-screens; while a solution of

iodine in bisulphide of carbon is opaque to luminous radiation, but allows the long waves to pass.

Röntgen rays are refracted like ordinary light, and very little trace of regular reflection has been detected. Moreover, it is only just recently, with great difficulty, that they have been made to show signs of such a typical property as polarization. Two plates of tourmaline seem to be as transparent to the rays when the axes of the crystals are crossed as when the axes are parallel. Such indications as these seem to be inconsistent with the identity in nature between Röntgen rays and ordinary light.

On the other hand, the rays suffer no deviation when acted on by a magnetic or by an electric field of force, a result which indicates that they are not projected particles carrying electric charges.

In the year 1896 Sir George Stokes suggested that an explanation should be sought in the hypothesis that Röntgen rays were single pulses travelling through the æther. Ordinary light is to be represented as a series of regular waves, succeeding each other at periodic intervals, many thousand waves, almost exactly similar to each other, following in order in a minute fraction of a second. According to this view, Röntgen rays must be regarded as single disturbances, propagated with the same velocity as light, but not followed by a train of waves. The thickness of the pulse, in which the whole disturbance is concentrated, is considerably smaller than the wave-length of any visible light.

On Maxwell's theory, now universally accepted, light is explained as a series of electro-magnetic waves; and we must therefore imagine the Röntgen pulses to be electro-magnetic also. But, as we have said, Röntgen rays are produced when a cathode ray strikes a solid object; and, if we take the cathode rays to be streams of electrified particles, it may be shown that electro-magnetic pulses will be started by their impact.

The investigation has already been given in §72 on page 205, when we were considering the origin and mode of propagation of light by the aid of Faraday's conception of tubes of force as developed by J. J. Thomson. It was there shown, that, by the sudden stoppage of a moving electrified particle, a single expanding spherical shell of electromotive force would start

and spread out from the particle as centre with the speed of light. Within the shell electric and magnetic forces exist, at right angles to each other, and at right angles to the direction of propagation of the disturbance. Stokes proved that such pulses would possess many of the properties shown by Röntgen rays.

Compared with the wave-length of ordinary light, the thickness of one of these pulses is very small, and will depend on the character of the arrest suffered by the electrified particle. The more sudden is the stoppage, the thinner and more intense will be the pulse shown in Fig. 97 on page 205, and the more pronounced will be the characteristic properties of the Röntgen rays. It is well known that the character of the rays depends on the degree of exhaustion of the bulb in which they are produced. The higher the exhaustion, the more penetrating become the rays. The very "hard" rays obtained with high exhaustions are absorbed by different kinds of matter in almost exact proportion to the density of the matter. This relation does not hold for the "softer" rays given by bulbs containing air at higher pressures.

**102.** The successful explanation of the production and properties of Röntgen rays is strong evidence in favour of the view that the cathode rays, from which they arise, are flights of electrified particles. Other evidence pointing to the same conclusion is also available, and this conception of the nature of cathode rays is now accepted universally.

A direct demonstration of the negative charge associated with cathode rays was given by Perrin. He showed that, when the rays within the discharge bulb were deflected by a magnet so that they fell, through a small hole in a metallic screen connected with earth, on to an insulated metallic cylinder connected with an electrometer, a strong negative electrification was imparted to the system. When the rays fell on other parts of the bulb, this electrification was not observed.

A less direct but more interesting method of inquiry has been used by J. J. Thomson. The cathode rays are subjected successively to an electric and to a magnetic field of force.

From the observed deflections, it is possible to calculate the velocity of the hypothetical electrified particles, to determine the sign of the electrification, and to measure  $e/m$ —the ratio of the charge  $e$  carried by each particle to the mass  $m$  of the carrying particle.

Let us imagine such an electrified particle moving in a straight path with uniform velocity. Let us apply a uniform electric field of intensity  $f$  at right angles to the direction of motion. The effect is clearly the same as the effect of gravity on a body projected horizontally. The mechanical force on the particle is  $fe$ , and the acceleration  $\alpha$  at right angles to the original motion is given by  $fe/m$ ; the particle describes a parabola. The displacement in the direction of the electric force is

$$\begin{aligned}s_e &= \frac{1}{2} \alpha t^2 \\ &= \frac{1}{2} \frac{fe}{m} t^2.\end{aligned}$$

During the time  $t$ , the particle moves with its original velocity  $v$  in the direction normal to the electric force, and traverses a path  $l$ , which is equal to  $vt$ . Hence  $t^2$  is  $l^2/v^2$ , and the displacement is

$$s_e = \frac{1}{2} \frac{fe}{m} \frac{l^2}{v^2}.$$

Thus the equation involves the velocity of the particle and the ratio  $e/m$  of the charge to the mass.

Now, instead of an electric field, let us apply to the moving particle a magnetic force  $H$  at right angles to the direction of motion. The particle with its charge  $e$  moving with a velocity  $v$  is equivalent to a current  $c$  passing along a path of length  $\delta l$ , and we have

$$ev = c\delta l.$$

The mechanical force on a current when placed in a magnetic field of induction  $B$  is  $Bc\delta l \sin \theta$  (p. 105); and, if the medium be non-magnetic, so that the magnetic force is identical with the induction, and if the magnetic force be at right angles to the direction of motion, so that  $\sin \theta$  is unity, the mechanical force on the particle is  $Hev$ . This force, according to Fig. 56

on page 105, is at right angles both to the magnetic force and to the direction of motion. Unlike the mechanical force due to the electric field, however, the force due to the magnetic field does not act constantly at right angles to the *original* direction of motion. It acts at right angles to the direction of motion *at each instant*. This characteristic is a property of circular motion, like the motion of a planet round the sun, or that of a stone whirled by a string. The centrifugal force is, in such cases, measured by  $mv^2/r$ , where  $r$  is the radius of the orbit. Hence

$$Hev = \frac{mv^2}{r},$$

or 
$$r = \frac{mv}{eH}.$$

In practice, only a small part of the circle is described, so that the path of the particle is fairly straight. Hence, by the well-known property of the circle, the deflection is

$$\begin{aligned} s_m &= \frac{l^2}{2r} \\ &= \frac{l^2 H e}{2v m}. \end{aligned}$$

In this manner we obtain a new relation between the two quantities  $v$  and  $e/m$ . Thus, by observing the magnetic and the electric deflections in a given length of path of the cathode rays, both  $v$  and  $e/m$  may be determined in absolute units.

In applying these results experimentally, Prof. Thomson used

Fig. 113.

the apparatus shown in Fig. 113. Two electrodes are fixed in a highly exhausted glass tube by means of platinum wires

fixed through the glass.  $C$  is the cathode, and  $A$  the anode. Through the anode, and through a disc  $B$  of similar form connected with the earth, are bored holes, about a millimetre in diameter. Thus beyond the disc  $B$  we have a narrow pencil of cathode rays, removed from the action of the potential gradient of the discharge, and therefore moving with uniform velocity. The rays fall on the screen at the other end of the tube, and give rise to a bright phosphorescent spot at  $p$ . In the middle of the tube are fixed the two parallel plates  $D$  and  $E$ , which may be connected with the opposite terminals of a battery of voltaic cells in order to establish an electric field between them. When the rays pass out from between the plates, they leave the electric field and proceed in straight lines. From the deflection  $pp'$  at the end of the tube, the deflection  $s_e$  in the field of force might be obtained. The method adopted, however, was to apply simultaneously the electric field and a uniform magnetic field, due to an external electro-magnet, which produced a mechanical force on the rays in the opposite direction to that due to the electric field. The magnetic field was adjusted till no deflection occurred. Then the mechanical forces must be equal and

$$fe = Hev$$

or

$$v = \frac{f}{H}.$$

From the displacement  $s_m$  in a uniform magnetic field, the value of  $e/m$  was then obtained by means of a relation equivalent to the equation given above,

$$s_m = \frac{l^2 H}{2v} \frac{e}{m}$$

or

$$\frac{e}{m} = \frac{2vs_m}{l^2 H}.$$

The results of these experiments show that the velocity of cathode rays is not a constant. It varies even in the same discharge. This is shown by the fact that the magnetic field causes the pencil of rays to spread out, so that the patch of light is larger when deflected than when undeflected. The velocity varies still

more when the pressure or the nature of the residual gas is changed, and values ranging from about  $2 \times 10^9$  to  $4 \times 10^9$  centimetres per second have been obtained. On the other hand, the quantity  $e/m$  appears to be constant. Whatever be the pressure or nature of the gas, and whatever metal be used as electrode, the value of  $e/m$  is about  $7.7 \times 10^6$ , and that of  $m/e$  about  $1.3 \times 10^{-7}$ .

Now, in liquid electrolytes, the passage of one electromagnetic unit of electricity evolves about  $10^{-4}$  grammes of hydrogen (p. 224). Hence the value of  $m/e$  is about  $10^{-4}$  and that of  $e/m$  about  $10^4$ . It follows that for the particles of cathode rays the value of  $e/m$  is about 800 times as great, and the value of  $m/e$  about 800 times as small, as the corresponding quantities for the hydrogen ion in the electrolysis of liquids. We shall see later how to determine the charge on gaseous particles similar to those of the cathode rays. It will be found that the charge is identical with that on a monovalent ion in a liquid electrolyte. The result stated above then shows that the mass of a cathode ray particle is about the 800th part of the mass of a simple hydrogen ion, that is of a hydrogen atom.

**103.** As already stated, in normal conditions, air and other gases are very good insulators; and an electrified body suspended in air will lose its charge only with extreme slowness if precautions be taken to prevent conduction along the supports. The gold-leaf electroscope shown in Figure 114, which is here reinserted from p. 19 for convenience, contains an ingenious device, due to Mr C. T. R. Wilson, for preventing such leakage. The brass plate *D*, to which the gold-leaf *C* is attached, is held in position by the bead of sulphur *A*, which is a very good insulator. The sulphur-bead is fused to a brass rod, which passes through the ebonite plug at the top of the instrument and serves to suspend the sulphur-bead and the gold-leaf system. The gold-leaf is charged by means of the moveable wire *EB*,

Fig. 114.

which may be brought into contact with the plate *D* and then again removed. Any leakage from the gold-leaf along the supports must take place over the sulphur-bead *A* to the brass rod which suspends the bead. Now, this rod may be connected permanently with the pole of the battery used to charge the wire *EB* and the gold-leaf. Hence, when first charged, the gold-leaf is at the same potential as its supports, and there is no tendency for leakage to occur. As the gold-leaf loses its charge through the air, its potential sinks below that of the supporting rod, and any leakage must tend to restore the charge of the leaf instead of to abstract it. While the gold-leaf is near its original potential, the difference of potential between it and its supports will be very small, and the usual slight leakage is much reduced as well as reversed in direction.

Even with the precaution just described, the gold-leaf system is found to lose its charge, though many hours may pass before the charge is half dissipated. It follows that air in its normal condition must possess some conductivity. The effect is so small, however, that it is probable that its phenomena would never have been coordinated or explained had we not possessed means of increasing it at will. It has long been known that a charged body is diselectrified by contact with the hot gases of a flame, and, soon after Röntgen's discovery of X rays, it was noticed that an electroscope was discharged rapidly when the rays passed through the air surrounding it. A similar result is obtained by the incidence of ultra-violet light on a metallic surface, or by the neighbourhood of radioactive substances. By any of these methods, the electrical conductivity of gases may be increased very greatly.

The nature of the conductivity thus imparted is indicated by the fact that a gas, which has been under the influence of one of the agencies mentioned above, does not lose its newly acquired properties immediately. It may be blown about from place to place, and still will discharge an electroscope. These effects may be investigated by an arrangement similar to that shown in Figure 115. The Röntgen rays are produced in a bulb placed within a box covered with thick lead except at the window *B*, through which alone the rays find an exit. Thus the electroscope

*A* is screened from the direct action of the rays. Through the walls of the electroscope two tubes pass, and, by attaching a water-pump to one of them, a slow current of air, drawn from the region traversed by the X rays, may be sucked through the electroscope.

Fig. 115.

In these circumstances, the electroscope is found to lose its charge, while, if the current of air be stopped, or if the rays be cut off, the charge is retained. If a plug of glass-wool be placed in the tube *C*, the electroscope is not discharged by the current of air drawn from the region subject to the action of the rays. The conductivity of the air is also removed by bubbling the air through water, or by passing it through a metallic tube of fine bore. The same effect is produced by sending the air through an electric field, which may be produced by means of a metallic tube of large bore, along the axis of which is stretched an insulated wire. The tube and wire are connected with the opposite terminals of a battery of some hundreds of small accumulator cells, the tube being also joined to the earth. After passing through such a tube, the conductivity of the air disappears.

These phenomena suggest that the conductivity of air is to be explained by the supposition of the presence of charged particles, somewhat of the same nature as the ions of liquid electrolytes. In liquids, the ions are permanent, but in gases some ionizing agency is necessary for their production. Moreover, when formed, the ions of gases are removed by contact with solids (glass-wool or the walls of a fine tube), by contact with liquids, or by the action of an electric field. Even without such processes, the ions gradually disappear spontaneously. Regarding the ions as oppositely elec-

trified parts of molecules, it is natural to refer this disappearance to recombination under the attractive forces of the opposite charges. This hypothesis may be developed mathematically, and its consequences subjected to experimental examination.

Let  $q$  denote the total number of ions, positive and negative, produced per second in one cubic centimetre of the gas by the action of the ionizing agency. If each uncharged molecule gives rise to one positive and one negative ion, the number  $n$  of positive ions which exist at any moment in unit volume is the same as the number of negative ions.

Now, on the principles of the dynamical theory of gases, the number of collisions per second between opposite ions is proportional to the product of their concentrations, that is, to  $n^2$ . If a certain fraction  $\beta$  of the collisions result in the formation of a neutral system, the number of ions which disappear per second in a cubic centimetre is  $\beta n^2$ . But  $q$  is the constant rate of ionization, and the resultant total rate at which ions are formed is given by

$$\frac{dn}{dt} = q - \beta n^2.$$

In a steady state, when the ionization is constant,  $dn/dt$  vanishes, and we have

$$q = \beta n^2.$$

If the ionizing agency be removed,  $q$  becomes zero, and the rate of decay of the ionization is represented by the equation

$$\frac{dn}{dt} = -\beta n^2,$$

which, when integrated, gives

$$\frac{1}{n_0} - \frac{1}{n} = \beta t,$$

where  $n_0$  is the initial number of ions, and  $n$  the number after a time  $t$ .

The rate of recombination of gaseous ions may be investigated by an apparatus used by Prof. Rutherford and shown in Fig. 116. A slow current of dry gas is drawn through a plug of cotton-wool to remove particles of dust, and then through a long metallic tube.

At  $T$ , the gas is subjected to the action of an ionizing agency such as X rays, or the radiations from a radioactive substance such as oxide of uranium. At different points along the tube, insulated

Fig. 116.

electrodes,  $A$ ,  $B$ , etc., are inserted, and, by connecting one of these with one terminal of a battery of accumulators, and the earthed tube with the other terminal, the conductivity of the gas at the point may be measured. A gauze screen at  $D$  shields the region near  $T$  from the electric field, and serves to prevent the direct abstraction of ions by the electric force at  $A$  or  $B$ . If the tube be of wide bore, the loss of ions caused by diffusion to the walls is small, and the decrease in conductivity of the gas is due to recombination alone. Knowing the velocity of the current of gas along the tube, the effect of time on the ionization may be investigated.

The results of such experiments agree well with the equations given above, and are thus consistent with the theory on which those equations are based. The quantity  $\beta$  is found to be constant, and to have a value of about  $3000e$ , where  $e$  is the charge on a gaseous ion. This quantity  $e$  has been shown, by methods to be described hereafter, to be about  $3.4 \times 10^{-10}$  electrostatic units. Thus  $\beta$  is about  $10^{-6}$ , and if  $10^6$  ions be present per cubic centimetre, half of them recombine in about one second.

**104.** In metallic conductors the current is proportional to the electromotive force applied, in accordance with Ohm's law. In liquid electrolytes the same relation holds good, provided the effects of the polarization of the electrodes be eliminated. In order to examine the relation between the current and the difference of potential in gases, the apparatus indicated in Fig. 117 may be employed. The air between two parallel metallic plates  $AB$  is exposed to Röntgen rays, or to the radiation from some radioactive material. One plate,  $B$ , is connected with one pair of quadrants of a quadrant

Conductivity  
of gases.

electrometer (p. 45) the other pair of quadrants being connected with earth. The second plate *A* is joined to one pole of a battery of cells, of which the other pole is put to earth. At first, the opposite pairs of quadrants are connected together. When they

Fig. 117.

are disconnected, the conductivity of the gas enables the battery to charge up one pair of quadrants, and thus the rate of movement of the needle of the electrometer measures the current through the gas. By changing the number of cells in the battery, the relation between the potential-difference and the current may be investigated.

For a small potential-difference, it will be found that a proportional current flows—the conduction conforms to Ohm's law, and, near the origin, the curve between *C* and *E* is a straight line. As the potential-difference is increased, however, the current rises more slowly, till a limit is reached, and the curve becomes almost horizontal. On the analogy with the shape of the curves of magnetization (p. 83) the current then passing through the gas is known as the saturation current. It remains constant till the potential-difference is increased nearly to the value at which a spark passes, when a rapid increase of current again occurs.

Figures 118 and 119\* show the relation between potential difference and current, when the ionization is produced by radioactive substances. The saturation current is reached with a much

\* Rutherford's *Radioactivity*.

Fig. 118.

Fig. 119.

lower voltage in the case of the small ionization produced by uranium than with the large ionization due to radium.

While the current is at the saturation value, it is independent of the intensity of the applied electromotive force. This fact facilitates the determination of the relative ionization of a gas under different conditions. It is only necessary to know that the potential-difference lies within the wide limits corresponding with the saturation current, in order to measure the ionization by the current passing. The current may be measured by the rate of deflection of the needle of a quadrant electrometer, or by the rate at which the gold-leaf of an electroscope falls, as the charge thereof is lost by conduction through the gas.

If we assume that the ionizing agent acts uniformly everywhere between the plates, a condition approximately realized with some difficulty, a simple theory of this subject may be given.

Let  $q$  ions per second be produced per cubic centimetre between parallel plates at a distance of  $l$  centimetres from each other. When no electric field is established, the actual number  $n$  of ions present per cubic centimetre depends on a balance between the rates of production and recombination, and (p. 286)

$$q = \beta n^2.$$

If we apply a potential-difference  $E$ , small enough not appreciably to affect the total number of ions present, the conduction is similar to the convection of ions in liquids contemplated by Kohlrausch's theory (p. 235). The current  $c$  per square centimetre of the plate is given by the product of the number of ions per second crossing unit area normal to the motion, the charge  $e$  on each ion, and the potential-gradient  $E/l$ . Hence

$$c = ne(u + v) \frac{E}{l},$$

where  $u$  and  $v$  denote the mobilities of the ions, *i.e.* their velocities under unit potential-gradient.

For higher potential-differences, we must take into account the removal of ions from the field by the action of the current. The number of ions produced per second in a prism of unit cross area and length  $l$  is  $ql$ . The maximum current  $C$  will be obtained when all these ions are driven to the electrodes by the

electric forces before appreciable recombination has taken place. Thus

$$C = qle,$$

and the ratio of any very small current to the maximum current is given by

$$\frac{c}{C} = \frac{n(u+v)E}{ql^2}.$$

But  $q$  is  $\beta n^2$ ; hence, eliminating  $n$ ,

$$\frac{c}{C} = \frac{(u+v)E}{l^2 \sqrt{q\beta}}.$$

On the right-hand side of this equation, every term except  $E$  is constant. Hence, as experiment shows, a small current should be proportional to the applied potential-difference.

The saturation current,

$$C = qle,$$

increases with the rate of ionization, and with the distance between the plates. Thus, with a constant high potential-difference, the current through a gas is increased by separating the plates, a paradoxical result, which is explained when we remember that, with a saturation-current, all the ions are used up as soon as formed; an increase of space between the plates then gives more room for the action of the ionizing agency, and increases the number of ions available.

**105.** The sum of the opposite velocities of the complementary ions may be determined by a method based on the equations just given.

Mobilities of  
gaseous ions.

If  $u$  and  $v$  denote the ionic mobilities of the positive and negative ions respectively, that is, the velocities with which they move under unit potential-gradient, the current-density  $c$ , when it is small, is given by the equation

$$c = ne(u+v) \frac{E}{l},$$

where  $n$  is the number of ions per unit volume, each ion carrying a charge  $e$ , and  $E/l$  is the potential-gradient. The current per unit area of two plates (Fig. 117) may be determined by observing

the rate of deflection of the needle of an electrometer of known capacity. The quantity  $ne$  may be found by a second experiment. The ionizing agent, let us suppose it to be Röntgen rays, is allowed to act till the gas has reached a steady state. Then, at the same instant, the rays are switched off, and a very high potential-difference is applied between the plates. All the ions which, at the instant, exist between the plates are swept to the electrodes before appreciable recombination can take place. The negative ions alone go to the plate  $B$  connected with the electrometer, which thus receives a total charge equal to  $nel$ , where  $l$  is the distance between the plates. This charge  $Q$  may be measured in absolute units by the electrometer, and, combining the results of the two experiments, we have

$$\frac{c}{Q} = \frac{(u+v) E}{l^2},$$

whence  $u+v$  may be calculated.

By this method Rutherford measured the sum of the ionic mobilities of different gases at atmospheric pressure. The gases were not specially dried.

Gas	$u+v$ in cm./sec.	Gas	$u+v$ in cm./sec.
Hydrogen	10.0	Carbon dioxide	2.15
Oxygen	2.8	Sulphur dioxide	0.99
Nitrogen	3.2	Chlorine	2.0
Air	3.2	Hydrochloric acid	2.55

The mobilities of the individual ions cannot be calculated by this method alone. The ratio of the velocities, which was determined for liquid electrolytes by Hittorf's migration experiments, must also be obtained.

A method of so doing, due to Zeleny, consists in finding the electric force required to push an ion against a stream of gas, moving with a known velocity in the opposite direction. The velocity of the negative ion is, in general, higher than that of the positive, the ratios being

Gas	$v/u$	Gas	$v/u$
Air	1.24	Hydrogen	1.14
Nitrogen	1.23	Carbon dioxide	1.00

By combining these results with those given by Rutherford, the individual mobilities may be calculated.

The individual mobilities have also been determined by direct observation in various ways. Zeleny again used a blast-method. He passed a stream of gas along a tube, and measured the distance that stream carried an ion forward while it was passing from the circumference of the tube to the axis under the influence of a radial electric force.

Gas at 760 mm. of mercury pressure	Temp. in deg. Cent.	Velocities in cm./sec. per volt per cm.		Ratio of velocities of negative and positive ions
		Positive ion	Negative ion	
Air, dry	13.5	1.36	1.87	1.375
„ moist	14	1.37	1.51	1.10
Oxygen, dry	17	1.36	1.80	1.32
„ moist	16	1.29	1.52	1.18
Carbon dioxide, dry	17.5	.76	.81	1.07
„ „ moist	17	.82	.75	.915
Hydrogen, dry	20	6.70	7.95	1.19
„ moist	20	5.30	5.60	1.05

It will be seen that, in most cases, these results agree with the sum of the opposite ionic mobilities given above. Other methods, also, give values in accordance with these figures.

It is found that, till the pressure sinks to a small fraction of an atmosphere, the velocity of an ion varies inversely as the pressure of the gas through which it moves. The resistance to the motion of the ion is thus proportional to the density of the gas, or to the number of collisions between the ion and the molecules of the gas. It is interesting to note that the ordinary viscosity of a gas is independent of the pressure. Thus the motion of a gaseous ion is not analogous to that of a large body moving through a viscous fluid, but to that of one molecule of a gas working its way through the others.

As the pressure sinks to that corresponding to about 10 millimetres of mercury or less, a rapid increase occurs in the mobility of the negative ion. No similar large change is observed for the positive ion. At these low pressures, some of the negative ions seem to resemble the minute structures detected in cathode rays. At higher pressures it is natural to picture the negative ion as

composed of one of these corpuscles, with one or more neutral molecules attached.

**106.** The cathode rays, as we have seen, consist of a flight of negatively charged particles. When passing through a gas, these flying particles produce ionization, as may be demonstrated by means of the apparatus of Figure 113 on page 281. If some residual air be left in the tube, and a difference of potential be applied between the plates *C* and *D*, no current will pass between the plates till the cathode rays are turned on, when a considerable current may be observed. Similar particles are emitted by some radioactive bodies, and these particles also produce ionization when passing through a gas.

Such phenomena suggest that the flying particles ionize some of the molecules of the gas by virtue of the collisions which must occur, and this idea has been adopted and developed by many physicists.

When a potential-difference is established between two electrodes separated by a layer of gas, the few ions, which always seem to be present, are put in motion. The lower the pressure of the gas, the longer is the free path of an ion before it collides with a molecule of the gas, and thus the greater is the velocity acquired by the ion, and the greater is the shock of a collision when it does come. If the pressure be so low that some of the negative ions are free corpuscles, very high velocities will be reached between the collisions. In such cases, it is clear that the original negative ions will produce new ions by collision, just as do the cathode rays. These secondary ions may themselves produce tertiary ions, and so on. The result will be that a continually increasing supply of ions is forthcoming, and eventually a continuous electric discharge passes through the exhausted gas.

In this stage, the current is, of course, much greater than the usual saturation current of Figures 118 and 119 on page 289. These further phenomena have been studied from this point of view by Townsend, who explains all spark-discharges by similar considerations. Figure 120 shows a complete curve between the voltage as abscissa and the current as ordinate. Here the saturation

current extends from 700 to 1100 volts, and a rapid increase is seen beyond that point.

Fig. 120.

At atmospheric pressures, the potential-gradient required to produce ions by collision and start the spark is very great—some 30,000 volts per centimetre. The first spark facilitates the passage of others, probably by leaving some ions in its path, and by the increase in ionic mobility due to rise of temperature. Hence we reach an explanation of the phenomena of the electric arc, which is started by contact between the carbons, and persists as they are separated from each other.

In vacuum tubes (Figs. 110 and 111, p. 275), the high potential-gradient near the cathode causes the negative ions to start with very high velocities. J. J. Thomson and others have framed theories on the lines indicated to explain the complicated phenomena observed in such tubes.

107. We have stated that the electric charge on an ion of a gas is equal to that on a monovalent ion in a liquid electrolyte. We must now describe the experiments by means of which this result has been established.

The first series of experiments deal with the condensation of water-vapour on gaseous ions as nuclei. Long ago it was shown by Aitken that particles of dust facilitated the condensation of clouds, so that air would remain supersaturated when suddenly expanded adiabatically, if no dust were present. These results were extended by C. T. R. Wilson, who showed that, when the dust was removed by a few preliminary expansions, an expansion in

Gaseous ions  
as condensa-  
tion nuclei.

volume from 1 to 1.38 was needed to produce a dense cloud. If the gas were ionized by X rays, or by the radiation from radioactive substances, the cloud formed at an expansion of 1.25, while, by separating the ions by an electric field, it was shown that, although negative ions alone gave a cloud at an expansion of 1.28, positive ions needed an expansion of 1.31.

This greater efficiency of the negative ions as condensation nuclei may have a meteorological significance. Negative ions may be removed from the air by rain, leaving the air positively electrified.

The upper surfaces of Wilson's clouds are usually sharply defined, and thus the rate at which the cloud settles down, that is, the velocity of fall of its drops through still air, may be determined. Many years ago, Sir George Stokes investigated mathematically the friction on a sphere moving slowly through a viscous fluid, and showed that its value was  $6\pi r\mu v$ , where  $r$  is the radius of the sphere,  $v$  its velocity, and  $\mu$  the coefficient of viscosity of the fluid. The downward force due to the weight of the sphere is  $\frac{4}{3}\pi r^3(\rho - \sigma)g$ , where  $\rho$  is the density of the sphere and  $\sigma$  that of the fluid. In this case  $\sigma$  is small compared with  $\rho$  and may be neglected.

Now, as the drop falls, its velocity increases at first, and the frictional force increases with it. The weight keeps constant, and eventually the two forces will be equal and opposite. The sphere will then fall with a constant or limiting velocity  $v_1$ . We now have

$$6\pi r\mu v_1 = \frac{4}{3}\pi r^3\rho g,$$

or

$$r^2 = \frac{3}{2} \frac{\mu v_1}{\rho g}.$$

Thus the radius of the rain-drops may be estimated by observing the rate of fall of the cloud.

By calculation from the known expansion used, and the total volume of the vessel, we may find the total mass and volume of the water condensed in the cloud. Dividing the total volume by the volume of each drop, we obtain the number of drops formed. If the ions be not too numerous, each ion acts as a nucleus of condensation, and the number of ions is equal to the number of drops produced.

Using Wilson's method of condensation, J. J. Thomson deter-

mined the number of ions per cubic centimetre of a gas. Their velocity under unit potential-gradient is known by the investigations described in § 105. Hence, by measuring the current  $c$  through the gas when acted on by a known potential-gradient  $E/l$ , it was possible to calculate  $e$  the ionic charge from the equation (p. 290)

$$c = ne(u + v)\frac{E}{l}.$$

The latest and best value of  $e$ , given by experiments made in 1901–2, is

$$e = 3.4 \times 10^{-10} \text{ electrostatic units of electricity.}$$

In Chapter X, page 227, we calculated the charge on one hydrogen ion in liquid electrolytes, and found that the probable mean value was about  $2.1 \times 10^{-10}$ . Within the limits of experimental error the charge on a gaseous ion is equal to the charge on a monovalent ion in a liquid electrolyte.

**108.** If an ionized gas be passed through a fine metallic tube, it emerges in a non-conducting state. The ions diffuse to the sides of the tube, and either adhere to the walls, or give up their charges. By passing a stream of ionized gas through such tubes, measuring the saturation current through the gas, before and after the passage, and correcting for recombination on the way, Townsend determined the coefficients of diffusion of ions into different gases.

The number of ions which pass across any unit area at right angles to the axis of  $x$  is proportional to the difference in concentration  $n$  at two points on opposite sides of the area, and may be written as  $Ddn/dx$ , where  $D$  is defined as the coefficient of diffusion. We may regard the ions as moving parallel to the axis of  $x$  with an average velocity  $\frac{1}{n} Ddn/dx$ . The ions, being in the gaseous state, will exert a partial pressure  $p$ , which, at constant temperature, is proportional to the number of ions. The average velocity may therefore be written as  $\frac{1}{p} Ddp/dx$ . But  $dp/dx$  is the force along  $x$  acting on unit volume of the gas; thus the velocity with which the ions move under unit force is  $D/p$ . If the ions be

Diffusion of  
ions.

exposed to an electric field of intensity  $f$ , the mechanical force on the ions in unit volume is  $fne$ , where  $e$  is the ionic charge. Hence, if  $u$  be the velocity of an ion in a field of unit intensity,

$$u = ne \frac{D}{p}.$$

Now  $n/p$  is the same for all gases at the same temperature, and the ions are gaseous. Thus, if  $N$  be the number of molecules in a cubic centimetre of air at the normal pressure  $P$ ,

$$u = eD \frac{N}{P}.$$

From the known values of the ionic mobilities, we know  $u$  in this equation, and Townsend's experiments give us  $D$ . The value of  $P$ , the atmospheric pressure, is about  $10^6$  dynes per square centimetre, and thus  $Ne$  may be found. Its value proves to be identical for all gases examined, air, oxygen, hydrogen, and carbon-dioxide, and the mean result is

$$Ne = 1.24 \times 10^{10}.$$

Now, in liquid electrolytes, one electromagnetic unit of electricity, or  $3 \times 10^{10}$  electrostatic units, liberates 1.23 cubic centimetres of hydrogen at  $15^\circ \text{C}$ . and a pressure of 760 mm. of mercury. In solution, these  $1.23N$  molecules exist as  $2.46N$  ions, and, if  $e'$  be the charge in electrostatic units on the ion of hydrogen in liquids,

$$2.46 Ne' = 3 \times 10^{10}.$$

Thus

$$Ne' = 1.22 \times 10^{10}.$$

Therefore as before we may conclude that the charge on a gaseous ion is identical with the charge on a monovalent ion in liquid electrolytes. Unlike the ions of liquids, which possess charges proportional to the valency, the charges on gaseous ions are independent of the nature of the gas.

**109.** In every case examined by these methods the charge on a gaseous ion seems to be the same as the charge on a monovalent ion in liquid electrolytes. Now, as we saw above, the negative ions in highly exhausted tubes—

The nature  
of gaseous  
ions.

the cathode rays—consist of negatively electrified particles, moving with velocities about one-tenth that of light, and possessing a

mass / charge ratio equal to about the eight-hundredth part of that of the hydrogen ion in liquids. If we assume that, here also, as in all other cases, the charge is equal to that of the liquid hydrogen ion, it follows that the mass of the cathode ray particle is about the eight hundredth part of that of the hydrogen atom.

It is most important that such a striking result should be confirmed in cases where both  $e$  and  $m/e$  can be measured for the same particles. Such a case has been found by Thomson in the ions due to the incidence of ultra-violet light on a metal placed in a highly exhausted vessel.

A zinc plate is illuminated with ultra-violet light, and placed opposite and parallel to a second metallic plate connected with an electrometer, the gas surrounding the apparatus being exhausted to a very low pressure. An electric force is established between the two plates, and the negative ions, produced at the zinc plate, are by this force urged towards the second plate. If no other agency were at work, all the negative ions would reach the second plate, and transfer their charges to the electrometer. Now let us imagine that a magnetic force is applied at right angles to the electric force and parallel to the planes of the plates. The magnetic force will deflect the negative particles from their original straight course, and their path becomes a cycloid. They travel out from the zinc plate, curve round, and approach it again. If the second plate is placed near enough to the first to intercept this curved orbit, all the ions will still reach the plate connected with the electrometer, and the rate at which that instrument gains negative electricity will not be affected by the presence of the magnetic field. If, however, the electrometer plate be moved away from the zinc plate till it lies beyond the path of the ions, it will receive none of them, and the establishment of the magnetic force should stop completely the supply of negative electricity to the electrometer. If  $X$  be the electric force and  $H$  the magnetic force, theory shows that no ions should cross the space between the plates if the distance between them exceeds  $2Xm/eH^2$ , while below that distance the addition of the magnetic force  $H$  should produce no effect on the rate of gain of negative charge by the electrometer.

The experiments which Thomson carried out by this method

showed that no such sudden change could be produced. As the distance was diminished, or the magnetic field increased, at first the effect of putting on or taking off the magnetic force was small. Then a stage was reached at which a considerable effect was produced; while finally, in a third stage, the magnetic force cut off almost all the ions from the electrometer plate. This somewhat gradual change is explained if we suppose that the negative ions are not all formed at the surface of the zinc plate, but that, as the primary ions there produced move forward under the action of the electric force, they produce new ions by their collisions with the molecules of the gas. The ions are thus formed, not exclusively at the surface of the plate, but throughout a thin layer of gas near the plate.

These considerations indicate that, in the experiments we are now describing, the limit of the second stage, in which some but not all of the negative ions are stopped by the magnetic field, gives the distance at which those ions coming from the surface of the zinc plate just fail to get across the space between the plates. The expression given above then leads directly to a value for  $e/m$ , the ratio of the ionic charge to the ionic mass. Thomson found as the result  $7.3 \times 10^6$ , a number which agrees extremely well with that deduced for cathode rays, namely,  $7.7 \times 10^6$ .

With the negative ions produced by the incidence of ultra-violet light on a zinc plate, it is easy to repeat C. T. R. Wilson's experiments on the formation of clouds round ions as nuclei, and thus to determine the value of  $e$ , the electric charge associated with the same ions for which  $e/m$  has been obtained. The result shows that, as always, the charge is the same as the charge on a monovalent ion in liquid electrolytes; and therefore for the ions due to ultra-violet light, as for the cathode ray particles, the mass must be about the seven- or eight-hundredth part of the mass of the hydrogen atom. The result has been confirmed by Lenard, who used a somewhat different type of apparatus.

In all these experiments, then, we are compelled to admit the existence of particles smaller than the smallest of the known chemical atoms. These particles, to which Thomson has given Newton's old name of corpuscles, are associated with a quantity

of negative electricity, which plays the part of a true natural unit. Positive ions, while carrying an equal charge of the opposite kind of electricity, have never been found with these small masses; they seem always to be structures of at least atomic dimensions. We may provisionally explain the facts by the hypothesis that the corpuscle itself represents a unit charge of negative electricity. An atom of ordinary matter with one corpuscle beyond its normal number is an atom negatively electrified; an atom with a corpuscle detached from it is an atom positively electrified.

Isolated corpuscles are found in cathode rays, in the radiation from radioactive substances, and in gases at low pressures and high temperatures. As the temperature falls or the pressure rises, the negative ions approach the positive ions in size, and at ordinary pressures appear, by their coefficients of diffusion, to be at least of atomic size. The corpuscle must then be imagined to attach itself to one, or perhaps more, neutral molecules, and this complex structure to act as the negative ion.

We are now in a position to estimate the importance of the experiments which have shown that the mass of the corpuscle is independent both of the nature of the gas in which it is found, and also of the material of the electrode used in producing it. Not only must we conceive atoms to be made up of these more minute particles, but it is necessary to suppose that in all atoms, whatever be their nature, these particles are similar. The dream of an ultimate particle, common to all kinds of matter, has thus at length come true.

Further evidence is not wanting in support of this hypothesis. The absorption of ordinary light by different substances bears no relation to the density of the absorbing medium. Heavy materials like iron or glass, light bodies such as cork or water, may be either opaque or transparent. On the other hand, in the absorption of cathode rays, and of the corresponding rays which, as we shall see, are emitted by radioactive bodies, very different phenomena appear. A given thickness of any material, whether gas, liquid, or solid, absorbs these rays simply in proportion to its mass, entirely independently of any other property. Throughout an enormous range of density, various substances, including air, the heavy gas sulphur dioxide, paper, glass, silver, and gold, possess

absorption coefficients directly proportional to their densities. This remarkable relation is explained at once by the theory we are considering. If each atom of matter be composed of a number of corpuscles, and these corpuscles be extremely minute compared with the atom as a whole, it is clear that we must regard an atom as an open structure in which the vacant spaces are immense compared with the size of the tiny particles scattered throughout the atomic system under the controlling influence of their mutual forces. A collection of such atoms, forming, let us say, a thin plate of aluminium, might be quite impervious to other atoms as wholes—it might, in fact, be quite air-tight. The flight of isolated corpuscles in a cathode ray, however, if travelling fast, might be able to penetrate the plate here and there, the corpuscles finding their way between the atoms, or through the inter-corpuscular spaces in the structure of the atoms themselves. The corpuscles being all similar to each other, the relative densities of two substances, such as aluminium and air, must depend simply on the relative numbers of corpuscles which make up the atoms contained in unit volume of each material. The power, possessed by different kinds of matter, of stopping cathode rays, also, will depend simply on the number of such corpuscles contained in unit volume of the different absorbing media, for the particles in the rays will pass readily through the open structure of the atomic systems, but will be stopped by collision with the substance of the individual corpuscles which make up those systems. The absorbing powers must thus, on our theory as well as in fact, be proportional to the density of the material, and independent of all its other properties.

**110.** A flame, or the hot gases therefrom, will discharge an electrified body, and the air near an incandescent solid is found to be ionized. Elster and Geitel, O. W. Richardson, H. A. Wilson, and others have shown that, as a platinum wire is heated gradually, it begins to emit positive ions at a temperature corresponding to a low red heat. The investigation of the influence of a magnetic force shows that these ions vary in size, some probably being molecules of the gas, and others molecules of the metal or even dust disintegrated

Ions from  
incandescent  
bodies.

from its surface. As the platinum is heated still further, negative ions also come off, ultimately in large excess. In *vacuo* the negative leak from platinum and carbon filaments is very large—from carbon it may even amount to as much as an ampere of current from each square centimetre of surface. The negative ions are then of sub-atomic dimensions, and are identical with the corpuscles obtained by other means.

The emission of corpuscles at high temperatures is not confined to solids. Thomson finds that sodium vapour also gives off a large supply, and the effect seems to be common to all kinds of matter at a white heat. Carbon is particularly efficacious, perhaps because it can be raised to a higher temperature than can metals. It is easy to demonstrate the existence of a measurable current from one limb of the carbon filament of an ordinary incandescent lamp to an insulated plate placed between the limbs.

Owing to the emission of corpuscles by an incandescent wire or carbon filament along which a current flows, the effective current-carrying area of the wire is increased. In *vacuo* a considerable fraction of the current might pass through the space surrounding the wire, which must become filled with corpuscles. Although in gases at ordinary pressures the emission of corpuscles is less copious, still, ionization will occur to an appreciable extent just round the wire, and a part, though perhaps a small part, of the current will pass along outside the substance of the wire.

The phenomena we are now considering must have an important bearing on cosmical processes. The photosphere of the sun contains large quantities of glowing carbon, and this carbon will emit corpuscles until the resultant positive charge left on the sun exerts an electrostatic force great enough to prevent further emission. In this way a condition of equilibrium would be reached. Any local elevation of temperature would then cause a stream of corpuscles to leave the sun and pass into the surrounding space. When corpuscles pass through a gas with high velocity, they make it luminous, and Arrhenius has explained many of the periodic peculiarities of the Aurora Borealis by the supposition that corpuscles from the sun, due either to incandescence or to some other cause, stream through the upper regions of the earth's atmosphere.

**111.** The phenomena of electrolytic conduction through liquids, and of non-electrolytic conduction through metallic substances, must now be interpreted in terms of this corpuscular theory. The chemical decomposition of electrolytic solutions, which we have described in Chapter X, indicates that an electric transfer through such liquids involves a movement of the chemical constituents of the substance decomposed. In fact, as we have seen, that movement has been demonstrated experimentally, and the passage of the ions rendered visible. We must suppose, then, that the corpuscle forming the effective negative essence of the anion in liquid electrolytes is attached to an atom of matter. This atom may be associated with other atoms or molecules forming a complex ion, but the point is that the isolated corpuscle cannot slip from one atom to another, and thus carry an electric current through the liquid; the corpuscle cannot move without a corresponding movement of matter—of matter, that is, in its atomic or molecular sense.

Here again the motion of the positive ion involves the simultaneous passage of a particle of matter of at least atomic dimensions. The positive ion consists of an atom of the electrolyte with one of its corpuscles missing. A unit of negative electricity has been removed from it, that is, it is left with a positive charge. Electricity, on this hypothesis, is one, not two; the two so-called opposite electricities being perhaps an excess or defect of a single thing. Thus the nomenclature of the old "one fluid theory" is still appropriate. It is true that the meaning of the conventional names positive and negative should be reversed. But the signs conventionally attached to electric charges are a mere matter of historical accident. It is the old negative electricity which, from our present point of view, is the real corpuscle, and a positive charge means a deficiency in the proper number of the electrical units.

In metals, an electric current flows without chemical change in the substance of the conductor, so that, in this case, we must imagine the corpuscles to be freely mobile. They pass from atom to atom, and thus carry the current when an electromotive force acts. In the presence or absence of such a force, they may be regarded as existing within the metal in a state resembling in many ways the state of a gas in a closed vessel. Estimates have

The corpuscular theory of conduction.

been made of the number of corpuscles present in a given volume; of the velocity with which they move under an electric force; and of their mean free path within the metal, that is, of the average distance a corpuscle moves between its collisions with other corpuscles. As we have seen, when the metal is heated, the corpuscles begin to leave it, and stream away into the surrounding space. At any constant temperature, equilibrium is set up between the corpuscles leaving the metal owing to the effect of temperature and those drawn back again by the residual positive charge on the metal. We may look on the system as analogous to a liquid in equilibrium with its own vapour.

In Chapters III and IX we saw that it was necessary clearly to distinguish the electric current and the heating effect of the current from the flow of the energy by which the current was maintained. The energy passes through the surrounding medium, through the luminiferous æther. The current is merely the line along which the energy of the æther can be dissipated as heat.

A conducting wire must be regarded as a channel along which the free ends of a line or tube of electric force can move, and, when the poles of a battery are connected by means of a wire, the tubes of force in the surrounding air run their opposite ends on to the wire, pull those ends towards each other, and shut up. Other tubes are then pushed into the wire by their mutual transverse pressure, and are obliterated in turn. The tubes of force in the dielectric field are thus inclined to disappear, and the state of æthereal strain in that field tends to be relieved. Simultaneously, however, the battery endeavours to reassert the original distribution of tubes, and once more to set up the strain. In this way new tubes are constantly forming between the terminals of the battery, and are as constantly pushed into the connecting wire, where they vanish. When the connection is metallic, it is only the negative ends of the tubes, attached to the corpuscles, that move, the positive ends remain at rest. If, on the other hand, part of the circuit be composed of an electrolyte, in that part the positive ends of the tubes, being attached to mobile ions, move also.

The ionic theory of electrolysis gave a clear idea of the mechanism by which the slipping of the ends of the tubes of force occurred in conducting liquids, and the corpuscular hypo-

thesis gives us an equally vivid insight into the nature of the process within metallic circuits. The tubes, anchored by their ends to an ion in electrolytes or to a corpuscle in metals, drag their anchors. It is the slip of the anchors that constitutes the current, and the heat developed by the passage of the current is to be explained by the frictional resistance to the drag of the anchor, or to some other means of dissipating energy, such as inter-corpuscular radiation, not yet fully understood.

## CHAPTER XII.

### RADIO-ACTIVITY.

Radio-active substances. Classification of the radiations. Radio-active change. Radio-active emanations. Induced or excited activity. The energy of radio-active change. Theories of radio-activity. Radio-activity of ordinary materials. Electricity and matter.

**112.** THE discovery of the phenomena of radio-activity arose indirectly from the study of Röntgen rays, and the investigation of the new phenomena was rendered possible by the knowledge which was acquired previously and simultaneously of the conduction of electricity through gases.

Röntgen rays produce fluorescent effects on suitable screens; and it was natural to examine phosphorescent and fluorescent substances, to determine if they were the source of similar radiation. For some time no definite results were obtained; but, in the year 1896, M. Henri Becquerel discovered that compounds of the metal uranium, whether phosphorescent or not, affected a photographic plate through an opaque covering of black paper, even when no light had fallen upon the compounds previously.

It was soon found that, like Röntgen rays, the rays from uranium produced electric conductivity in air and other gases through which they passed. Compounds of thorium, too, were found to possess similar properties. In the year 1900, M. and Mme. Curie made a systematic search for these effects in a great number of chemical elements and compounds, and in many natural minerals. They found that several minerals containing uranium were more active than that metal itself. Pitch-blende, for instance, a substance consisting chiefly of an oxide of uranium, but containing

also traces of many other metals, was especially active. When obtained from Cornwall its activity was about equal to that of the same weight of uranium, but samples from the Austrian mines were found to be three or four times as effective. The presence of some more active constituent was thus suggested. To examine this point, the various components of pitch-blende were separated chemically from each other and their radio-activities determined. In this way, three different substances, radium, polonium, and actinium, all previously unknown, appear to have been isolated by different observers. Of these three the most active is the well-known radium, discovered by M. and Mme. Curie, working with M. Bémont.

Radium is obtained from pitch-blende, in company with the metal barium; and the two seemed at first to be connected chemically so intimately that the new substance was for a time called "active barium." However, a slight difference in the solubilities of some of their salts allows them to be separated gradually by a process of repeated fractionisation, the radium chloride and bromide crystallising out more readily than the corresponding compounds of barium.

These processes of chemical separation are remarkable for their use of the new property of radio-activity as a sole guide in the operations. After each reaction the activities of both the product and the residue were determined. It was thus settled whether the reaction just tried was effective, and in which of the substances separated by the reaction the property of radio-activity had been concentrated.

The quantity of radium present in pitch-blende is extremely small, many tons of the mineral yielding, after long and tedious work, only a small fraction of a gramme of an impure salt of radium.

An interesting point in these investigations is the extreme sensitiveness of the property of radio-activity as a test for the presence of those substances which possess it. A delicate electro-scope will show easily a leak of electricity with a substance having an activity of about the one-thousandth part of that possessed by uranium. The activity of pure radium has been estimated as about one million times that of uranium; and such radium is a definite,

well-marked chemical element, like other elements, forming salts and other chemical compounds, and giving strong bright lines when heated and examined with a spectroscope. Spectrum analysis has hitherto been the most delicate means at our disposal for detecting the presence of the chemical elements; but in the preparation of radium from pitch-blende its spectrum only began to appear when, in the prolonged process of fractionization, the product had reached an activity of about fifty times that of uranium. Thus it appears from these figures that the electroscopic method of detecting radio-active matter is many thousand times more sensitive than the most refined methods of spectrum analysis.

**113.** In the year 1899 Professor Rutherford, of Montreal, discovered that the radiation from uranium consists of two distinct parts. One part was found to be unable to pass through more than about the fiftieth of a millimetre of aluminium foil, while the other part would pass through about half a millimetre before its intensity was reduced by one-half. The first named, or  $\alpha$  rays, produce the most marked electric effects, while the more penetrating, or  $\beta$  rays, are those which affect a photographic plate through opaque screens. At a later date a third type of still more penetrating radiation, known as  $\gamma$  rays, was detected. These rays can traverse plates of lead a centimetre thick, and still produce photographs and discharge electroscopes. In proportion to its general activity, radium evolves all three types of radiation much more freely than uranium, and is best employed for their investigation.

The moderately penetrating, or  $\beta$  rays, can be deflected easily by a magnet; and Becquerel, who deflected them by an electric field as well, conclusively proved that they were projected particles charged with electricity. M. and Mme. Curie had shown previously by direct experiment the existence of a negative charge associated with these rays. Owing to their ionizing action, it is impossible to demonstrate that a body surrounded by air gains a charge when exposed to the rays. Such a charge would leak away as fast as it was acquired. But, by working in a very good vacuum, or by surrounding the body with a solid dielectric such as paraffin, the acquisition of a negative charge can be demonstrated by means of an

Classification  
of the  
radiations.

electrometer. Further investigation showed that the  $\beta$  rays behave in all respects like cathode rays, although they possess velocities greater than those of any cathode rays hitherto examined, velocities which have different values varying from 60 to 95 per cent. of the velocity of light. The  $\beta$  rays, then, are negative corpuscles.

Magnetic and electric fields which are strong enough to deflect considerably the  $\beta$  rays produce no effect on the easily absorbed  $\alpha$  rays. Although Strutt, in the year 1900, had suggested that the  $\alpha$  rays were positively charged particles, of mass greater than that of the particles which constitute the negative  $\beta$  rays, it was not till some time afterwards that their magnetic and electric deviations were demonstrated experimentally, and shown to be in the direction opposite to that observed with  $\beta$  rays. The mass of the carriers in the  $\alpha$  rays, as calculated from the deviations, appears to be about that of helium atoms—more than one thousand times greater than that of the negative corpuscles—but there is some doubt whether the positive charges on the X rays are permanent, and if not, the basis of the calculation is unsound. The velocity is about one-tenth of that of light. The very penetrating or  $\gamma$  rays have never been deflected, and it is supposed that they are different in kind to the other types, and, like the X rays discovered by Röntgen, consist of wave-pulses travelling through the æther with the velocity of light. On the analogy of the cathode rays, indeed, we should expect that such pulses would be started as a secondary effect of the  $\beta$  rays.

Each type of radiation is absorbed by matter of all kinds in direct proportion to the density. The  $\alpha$  rays, which can penetrate only some hundredth of a millimetre of aluminium, will be absorbed by passage through a few millimetres of air. About 95 per cent. of the total ionization produced by a layer of radium or uranium is due to the  $\alpha$  rays. Hence the ionization is much more intense in a layer a few millimetres thick lying next the radio-active material. This result is to be borne in mind in applying simplified theories, such as that given on page 290, to these cases. The potential-gradient, too, between two electrodes, on one of which is spread a layer of uranium or radium, will not be uniform, being less where the ionization, and consequently the conductivity, is greater.

In the present year, 1905, a new type of radiation has been

discovered. When radium or polonium is placed in a vessel exhausted to the highest possible degree by the aid of charcoal cooled with liquid air, the substance is found to emit very slowly moving particles, which impart a negative charge to a gold-leaf suspended within the vessel. These negative particles are absorbed by a much thinner layer of air than the  $\alpha$  rays, and, except in a good vacuum, are absorbed before they can be detected. It is not yet certain whether or not these slow-moving particles are an invariable accompaniment of  $\alpha$  radiation.

It is remarkable that the radio-activity of a substance as measured by the emission of  $\alpha$ ,  $\beta$ , and  $\gamma$  rays is not affected by changes of temperature. Heating to redness, or cooling in liquid air, equally seem to be, in general, without effect. Again, the radio-activity of any element appears to be independent of the compound in which that element is contained. In thin layers, when absorption by the substance itself is not involved, the activity of a given mass of radium is the same when present as chloride or as nitrate, while uranium the metal has the same activity when combined as uranium nitrate.

The property of independence of temperature seems to forbid the reference of the energy of radio-activity to any ordinary chemical changes, while the identity of the effect for an element in different compounds indicates that radio-activity is a characteristic property of the chemical atom.

**114.** The experiments just mentioned suggest that radio-activity is an atomic phenomenon. But, in the year 1900, Sir William Crookes found that, if uranium be precipitated from solution by means of ammonium carbonate, and the precipitate dissolved in an excess of the reagent, a small quantity of insoluble residue remained. This residue, to which Crookes gave the name of uranium-X, was found to be intensely active when examined photographically, while the re-dissolved uranium was photographically inert. Similar results were obtained by Becquerel, who found that, when put aside for a year, the active residue lost its activity, while the inactive uranium regained its original radiating properties.

In 1902 Rutherford and Soddy discovered a corresponding

effect with thorium, which may be deprived of part of its activity by precipitation with ammonia. The filtrate, when evaporated, yields a residue which is very radio-active. After a month's interval, however, this activity had disappeared, while that of the thorium had regained its initial value. The active residue, thorium-X, seems to be a distinct chemical substance, for it is only separated completely by ammonia. Other reagents which precipitate thorium do not separate it from thorium-X. On these grounds it was concluded that the X-compounds are separate bodies, which are produced continuously from the parent substances, and lose their activity with time.

The processes of loss and regain of activity were then studied in detail. We will take the case of uranium, which, in some ways, is simpler in its properties than thorium. Crookes and Becquerel measured the activity by the action of uranium on a covered photographic plate. The cover absorbs the  $\alpha$  rays, and hence the  $\beta$  rays alone are used in such experiments. If the electrical method be employed, all the types of rays may be studied. Rutherford and Soddy found that the non-separable activity of uranium was due to the emission of  $\alpha$  rays alone, while the activity of the uranium-X was due solely to  $\beta$  and  $\gamma$  rays.

The rates at which the activity of the uranium-X decayed,

Fig. 121.

and that of the separated uranium recovered, are shown in the curves of Figure 121. It will be noticed that the curves are complementary to each other; the activity regained by the uranium is, at any time, equal to that lost by the uranium-X. Again, we see that it is no more possible to change the total amount of radio-activity by chemical than by physical processes.

The activity of the uranium-X falls to half its initial value in about 22 days, and the residual half-activity again sinks to half in an equal period. This rate of change in a geometrical progression is typical of radio-active processes, the particular time-constant involved depending upon, and characterizing, the particular substance involved. Thus similar curves are obtained with thorium and thorium-X, but the time needed for the activity to become halved or doubled, in this case, is only 4 days. The determination of the rate of decay of radio-activity may be carried out easily by electrical measurements; it gives the most convenient and delicate test for the different radio-active substances, which may be distinguished from each other by this means.

In all such processes as those we are studying, the variable quantity changes by an amount per second proportional to the value of the variable at the beginning of the interval. Examples of this method of variation are given by the decrease in the pressure of the atmosphere as one ascends vertically from the surface of the earth, by the increase of a sum of money put out at compound interest, or by the decrease in the amount of a chemical compound which is dissociating, molecule by molecule, into simpler products. The likeness between radio-active changes, which, as we have seen, are probably atomic phenomena, and a mono-molecular chemical change is significant. It suggests that the X-products are formed by the dissociation of the chemical "atoms" of the radio-active elements.

Let  $I$  be the intensity of the activity of unit mass of uranium-X at the end of a time  $t$ . Then the rate of decay of activity is  $-dI/dt$ , and, by experiment, is proportional to  $I$ , the actual activity. Thus

$$-\frac{dI}{dt} = \lambda I,$$

where  $\lambda$  is a constant expressing the fraction of the activity lost in unit time.

If we integrate this expression, taking  $I_0$  as the initial activity, we get

$$\log_e \left( \frac{I}{I_0} \right) = -\lambda t,$$

which, by the nature of logarithms, may be written

$$\frac{I}{I_0} = e^{-\lambda t}.$$

On the theory which regards radio-activity as the accompaniment of the production of new substances, these equations denote the rates of formation and decay of the new radio-active material.

**115.** In the year 1900 Rutherford made another striking discovery. The radiation from thorium was known to be very capricious, being affected especially by slight currents of air passing over the surface of the active material. Rutherford traced this effect to the emission of a substance which behaved like a heavy gas having temporary radio-active properties. This emanation, as it was named, is to be distinguished clearly from the radiations previously described, which travel in straight lines with high velocities. The emanation diffuses slowly through the atmosphere, as would the vapour of a volatile liquid. It acts as an independent source of straight line radiations, but suffers a decay of activity with time, following the usual exponential law. Similar emanations are evolved by radium and actinium, but not by uranium or polonium.

The amount of emanation evolved by radio-active substances is extremely small. A minute bubble has been obtained from some decigrammes of radium bromide, but, in ordinary cases, the amount is much too small to affect the pressure in an exhausted vessel, or to be detected otherwise than by its property of radio-activity. It is usually obtained mixed with a large quantity of air, and can be transferred from one vessel to another with the air.

Its activity may be tested by introducing the air mixed with the emanation into a brass cylinder (Fig. 122) along the axis of which lies a brass rod fixed through an ebonite cork. The rod is

connected with an electrometer, and the cylinder with one terminal of a battery. From the rate of deflection of the needle of the

Fig. 122.

electrometer, the current through the gas, and thus the ionization due to the contained emanation, may be estimated.

The radio-active emanations seem to be very inert chemically; in this, they resemble gases of the argon group. They pass unchanged through acids or hot tubes, but are condensed at the temperature of liquid air, evaporating again as the tube is warmed.

By measuring the rates of diffusion of the emanations into other gases, their densities have been determined approximately, and found to be about one hundred times that of hydrogen.

The rates at which the activities of the emanations decay may be examined by storing a quantity of air mixed with emanation, and, at regular intervals, placing an equal volume of it in a testing cylinder such as that of Figure 122. If the ionization be measured immediately, it will represent the activity of the emanation alone, uncomplicated by the activity excited on solids by contact with the emanation—an effect which we shall examine presently.

The activity of the emanations is found to follow an exponential law of decay, and the curves resemble those for the X-products illustrated in Figure 121 on page 312. The radium emanation decays to half value in about 3·7 days, and the thorium emanation in about 1 minute.

Unlike the “straight line” radiations of the types  $\alpha$ ,  $\beta$ , and  $\gamma$ , the emanations are emitted much more freely from some compounds of the radio-active element than from others, while the rate of emission is largely dependent on physical conditions, such as the

temperature of the system. By a striking series of experiments, however, Rutherford has traced these differences to variations in the ease with which, after formation, the emanation escapes from the generating substance.

Let us consider these results in more detail. It is found, for example, that while the emanation is given off very slowly from dry and solid radium chloride, it is emitted freely from the same salt in solution. This allows the problem to be submitted to the test of quantitative experiment. The rate of decay of the radium emanation is known; its activity falls to half value in 3·7 days. Thus, the activity of the emanation stored in a solid radium salt reaches a limit, when its rate of decay becomes equal to the constant rate at which the emanation is produced by the radium. On the hypotheses that the emanation is formed at the same rate in the solid as in the solution, that it escapes from the solution as fast as it is formed, and that it does not escape appreciably from the solid, it is clearly possible to calculate the amount of emanation that should be stored in the solid, as compared with the amount produced and emitted by the solution in a given time.

The calculation shows that 463,000 times more should be stored in the solid than is emitted by the solution in one second. Now if, as supposed, the emanation is stored in the solid, this large amount will be liberated instantaneously when that solid is dissolved in water. Rutherford and Soddy measured this rush of emanation by its effect on an electroscope, and found that it was 477,000 times greater than the quantity afterwards developed by the solution in one second: a remarkable confirmation of the several hypotheses given above.

The effect of raising the temperature is similar to that of solution. When a solid radium compound is brought to a red heat, a rush of emanation takes place, which makes the initial emanating power some hundred thousand times greater than that of the cold solid. This high rate of emission, however, does not last; it, also, is due to the rapid escape of stored material.

By experiments such as these, the emanating power of radioactive elements has been brought into line with their other radioactive properties, and has been shown to depend only on the mass of the element present, whatever be the state of combination in

which that element exists, and whatever be the physical conditions under which the process occurs.

**116.** If a rod, such as that within the cylinder of Figure 122 on page 315, be exposed to the emanation of radium or thorium, it will itself acquire radio-active properties, especially if negatively electrified while in contact with the emanation. When withdrawn from the vessel containing the emanation, and placed in a testing cylinder as shown in the figure, it is found to ionize the gas.

Induced or  
excited  
activity.

Again, if a platinum wire which has become active by exposure to thorium emanation be washed with nitric acid it is unaffected. With sulphuric or hydrochloric acid, however, it loses nearly all its activity, while the acid, when evaporated, gives a radio-active residue. This result indicates that the excited activity on the wire is due to the deposit of some new type of radio-active matter, which has definite reactions with different chemical reagents. In the light of the conclusions at which we have arrived above, it is natural to interpret this new matter as a product of the disintegration of the emanation from which it arises.

For long exposures to the emanation, the decay of the excited activity on a solid surface follows an exponential law. For short exposures, more complicated curves are obtained. Figure 123 shows the rate of decay of the excited activity due to an exposure for a few seconds to radium emanation. At first sight it bears no resemblance to the regular logarithmic curve of Figure 121 on page 312, which is the typical example of radio-active change. Rutherford has shown, however, that this radium curve may be explained by the hypothesis that the radio-active matter undergoes three successive changes, each of which conforms to the usual exponential law. The first change, to which is chiefly due the rapid fall of the curve near the beginning, is half completed in about 3 minutes; the second change involves no radio-activity, and is half completed in 36 minutes; while the third change is again radio-active, the half value being reached in 28 minutes.

If the rod be exposed for a few seconds only, the first kind of excited activity alone is produced while the surface is in contact with the emanation. When the rod is removed, this

activity decays rapidly, and the matter to which it is due passes into a new kind, which, in its turn, gives rise to a third. This change, however, is not accompanied by radio-activity, or, at all events, by radio-activity measurable by ordinary methods. The third kind of matter again changes, and this time the process is radio-active once more. The simultaneous process of these three kinds of change gives rise to the complicated phenomena represented by the curve of Figure 123.

Fig. 123.

If the rod be exposed to the emanation for some hours, a balance between these different processes is reached, and the whole radio-activity decays, when the rod is removed, in an exponential manner with the time.

Soon after appreciable quantities of radium were available for investigation, Giesel drew attention to the fact that a radium compound gradually increases in activity after formation, and only

reaches a constant state after a month's interval. Similar phenomena have been observed by Curie and Dewar for the heat-effect. These results are explained readily if we consider the properties of the emanation as elucidated by the experimental evidence that has now accumulated.

When a salt of radium is dissolved in water, and the solution boiled, the emanation previously stored in the salt is evolved and removed. The residual activity of the salt is then found to be much diminished. This activity must include that due to the radium itself, and also the excited activity, which has been developed by the emanation, but is not removed with it. The effect of the excited activity decays rapidly; after a few hours it will nearly have vanished, and we then get the true activity of the pure radium salt alone, uncomplicated by that of the emanation, or by the excited activity which is produced by the emanation.

This residual, non-separable activity is found to consist entirely of  $\alpha$  rays, and, measured electrically, is about 25 per cent. of the normal activity of a radium compound after a month's existence; a normal activity which comprises the combined effects of radium, of the radium emanation, and of the excited activity.

Thus, radium itself, in producing the emanation, gives rise to  $\alpha$  rays and the newly-discovered slow-moving negative particles only; similar radiation is found to be the sole accompaniment of the changes suffered by the emanation, and by the first, transient kind of excited activity. The second kind of deposited matter is non-radio-active, but the third kind, decaying to half-value in 28 minutes, produces at least  $\alpha$ ,  $\beta$ , and  $\gamma$  rays.

A further change has been detected. Bodies exposed to the emanation of radium become radio-active, and a small part of this activity remains after the lapse of many months. It is probable that this represents the action of matter produced by the last kind of substance described above. Rutherford estimates the time-constant of this slowly decaying matter at about 40 years—an interval too long to hold out much hope of quick improvement in the state of the walls, furniture and tools in laboratories where radium has been freely handled, and, in consequence, delicate measurements of gaseous ionization have become almost impossible.

**117.** In 1903 Curie and Laborde drew attention to the remarkable fact that compounds of radium constantly emitted heat. They calculated from their experiments that one gramme of pure radium would emit about 100 gramme-calories of heat per hour. The rate at which this energy is emitted is unchanged by exposing the radium salt to high temperatures, or to the low temperature of liquid air, and certainly is not diminished even at the temperature of liquid hydrogen.

The emission of heat has been correlated by Rutherford with the radio-activity. Radium freed from its stored emanation, recovers its radio-activity as measured electrically at the same rate as its power of evolving heat, and the separated emanation shows variations in the heat developed corresponding with those observed in its radio-activity. The electric effects of the radio-activity being chiefly due to the  $\alpha$  rays, the heat effect also must chiefly be connected with, or dependent upon, the emission of  $\alpha$  rays.

**118.** The demonstration of the continual development of heat by compounds of radium led to many attempts to explain the source of this apparently unfailing supply of energy.

It was suggested that radio-active substances possessed the power of absorbing the energy of some unknown radiation streaming through space, and of giving it out again in the form of the observed rays. Against this view it has been pointed out that the radio-activity of radium is not affected by surrounding it with thick screens of lead, which, it was argued, would presumably absorb some of the incident radiation. Moreover, the radio-activity and emanating power have been shown to be the same when the radium salt is concentrated, as when it is dissolved or spread in thin films. Thus, parts of the radio-active substance itself, which, by hypothesis, absorb this unknown radiation, do not appreciably screen other parts from its effects.

Both these results, however, are possibly consistent with the hypothesis which supposes that the unknown radiation is absorbed only by radio-active substances. Thus lead would have no absorbing effect, or, at all events, none appreciable compared with that of radium. And the absence of screening by contiguous portions

of radio-active matter is explicable if the intensity of the unknown radiation be great; a minute fraction of it would then alone be absorbed by the small quantities of radium which are available for experiment.

But the hypothesis is to be rejected on other grounds. It may be true that there is no evidence against it: at present there is certainly none for it. It introduces a new unknown: it is unnecessary, and nothing more damning can be said of a scientific theory.

As a result of their experiments on the emanations, and the excited activity produced thereby, Rutherford and Soddy explained the energy of radio-activity as due to the disintegration of the radio-active atoms. The evidence for this revolutionary hypothesis may be summarized as follows:

(1) Radio-activity is always found accompanied by chemical change; new substances are always detected after radio-activity has been going on—substances which have distinct physical and chemical properties, different from those of the pre-existent substances.

(2) The rates of development and decay of these new substances, as measured by their radio-activity, always follow an exponential law, whereby the rate of change is proportional to the amount of reacting substance present at any instant. This implies that the change is of the nature of a dissociation, in which individual particles alone are concerned. If the change were one of combination, or of double decomposition between two particles, the rate of change would depend on the square of the concentration, and another law would hold.

(3) Radio-activity is a characteristic property of the element—it does not depend on the state of combination, nor, in general, on the physical conditions, such as temperature, which affect ordinary chemical changes so decisively. The conformity with the mono-molecular law of change indicates that single systems are dissociating; this further evidence points to the atoms as the systems involved.

(4) Since a gramme of radium emits 100 gramme-calories of heat per hour continually for many years at least, the total amount of energy liberated must greatly transcend the energy associated

with any known chemical change. Hence we are led once more to look within the atom for the source of energy, and to suspect that the store of internal atomic energy is very great—an idea long ago suggested on other grounds.

Let us then in terms of this new theory, restate the results which we have already described. All radio-active elements have very high atomic weights, the atom of radium, for instance, being about 225 times as heavy as that of hydrogen. Radio-active atoms are therefore very complex structures, and, on the theory we are considering, are capable of breaking down into simpler and lighter systems. The elements thorium and uranium contain some few atoms which, at any moment, are disintegrating. As we have seen, the activity of the pure separated thorium or uranium consists of  $\alpha$  radiation only. Thus, the essential process of the radio-activity of these rays consists in the emission of  $\alpha$  rays, the disintegration of each atom resulting in the projection of one or more  $\alpha$  particles with a velocity about one-twelfth that of light, while the residues break down into new and simpler atoms, which are themselves in a state of instability, and are known to us as thorium-X and uranium-X.

The further transformation of these bodies is very rapid, their activity disappearing in a time to be measured in days. It is probable, however, that in radium we possess an analogous substance, also an intermediate product in a state of instability, the life of which is much longer.

The energy of the  $\alpha$  particles is known, and hence it is possible to calculate the total amount of energy which a given mass of radium would emit if each successive radio-active change means the emission of one  $\alpha$  particle per atom. The heat evolution gives the rate of evolution of energy; thus the time needed for a mass of radium to diminish by one half, as its atoms one after the other disintegrate, may be estimated as about 1000 years. The primary substance, standing to radium as thorium stands to thorium-X, is at present uncertain; it may be one of the metals which are found in pitch-blende, and experiments made by Mr Soddy and by the writer seem to show that purified uranium salts, when kept for some months, develop slight traces of radium emanation.

As in the formation of the X-product, the essential process in

the radio-activity which accompanies its disintegration consists in the ejection of the positively charged particle which we recognise as an  $\alpha$  ray by its power of ionizing a gas through which it passes, and thus rendering that gas a conductor. The loss of this positive particle implies a change in the atomic residue, which now, in the case of uranium-X, seems to lose all radio-active properties, and therefore to pass out of reach of our present powers of observation.

In compounds of radium and thorium, however, we get the emanations as the next step in the process of atomic dissociation. These bodies also are unstable, that is, radio-active. They emit new  $\alpha$  rays, and produce the excited activity which is due to a deposit on the walls of the containing vessel. This deposit again breaks down, with the usual accompaniment of  $\alpha$  radiation, and passes through the successive changes we have studied above, in the course of which  $\beta$  and  $\gamma$  rays appear.

The quantities of matter involved in any radio-active change are excessively minute, and no other method at present known enables us to detect the final inactive products as they are formed. It is, however, not improbable that, by the slow accumulation of material which must of necessity go on when a radio-active body is kept for a long time, the inactive products will be obtained eventually in amounts sufficient to be distinguished by the spectroscope or even by ordinary chemical analysis. In this connection we must give due weight to the fact that in all radio-active minerals considerable quantities of the gas helium are occluded. Sir William Ramsay and Mr Soddy, by spectroscopic methods, have detected the presence of helium in the gases evolved from a sample of radium, originally prepared from pitchblende and kept as a solid for some months. The spectrum of helium was invisible when the emanation was first collected and examined, but it soon appeared and gradually increased in intensity with the lapse of time.

Similar results have been obtained by Dewar and Curie, who, moreover, appear to have traced the disappearance of a minute volume of the emanation. This has been explained by the idea that the resulting helium, being projected in the atomic state with great velocity, penetrated the glass walls of the vessel and

thus occupied no volume. The decrease in the volume of a minute quantity of emanation has also been observed by Ramsay and Soddy.

Such results are very suggestive: it seems difficult to avoid the conclusion that helium is one of the final products obtained by the disintegration of the radium atom.

**119.** A few years ago radio-activity was unknown. Now, it is difficult or impossible to find substances which show no signs of the property. Traces of the emanation of radium or, at all events, of an emanation possessing an identical rate of decay, have been detected in many deep wells, especially in the medicinal waters of Bath and Buxton; in many samples of earth and clay; and in the atmosphere, particularly in the air of caves and caverns.

A wire, negatively electrified and exposed to the air, acquires excited activity resembling in all respects that caused by exposure to radium emanation, and it is natural to conclude that the slight traces of conductivity found in gases in all circumstances are due to radiations from some radio-active material, near or far.

The ionization of a gas in an enclosed vessel might be referred to the presence of some slight trace of a radio-active impurity in the substance of the walls, or to a specific radio-activity of that substance itself. The solution of this problem is a task of much difficulty owing to the prevalence of traces of radium; but, careful experiments by N. R. Campbell and others now indicate that the nature of the ionizing radiations depends on the kind of metal used for the walls of the vessel, and favour the view that all substances are to some slight degree radio-active.

**120.** The success of Maxwell's electromagnetic theory of light indicated that, as we have seen on page 205, the atoms of material bodies, which, when incandescent, give rise to light, must contain electric systems capable of vibration. The frequency of undulation of a wave of light is too great for us to refer the origin of the waves to atoms vibrating as wholes within the molecules, and we are thus driven to look within the atom for the vibrating particles. The complexity of the light

Radio-activity  
of ordinary  
materials.

Electricity  
and Matter.

emitted by many incandescent elements shows that the structure of the atom must be very complex also, and that the electric systems, which by their movements emit the electromagnetic waves of light, must be capable of many modes of vibration.

To explain these phenomena, a theory was framed, chiefly by Lorentz and Larmor, whereby the atom was imagined to be composed of a number of electric units, called electrons, in rapid orbital movement. On this view, matter is a manifestation of electricity, and it was attempted to explain the further question thus raised by imagining an electron to be a centre of strain in the all-pervading æther, a place where, "to use a crude but effective image, the continuity of the medium has been broken and cemented together again without accurately fitting the parts."

If the waves of light take their origin from the acceleration of intra-atomic electrons, which, when in motion, must be equivalent to currents of electricity, a magnetic field should change the path of the electrons, and thus affect the nature of the radiation. By such reasoning the phenomenon of the doubling and tripling of spectral lines in a magnetic field was predicted before it was discovered experimentally by Zeeman.

When, by the experiments described in the last chapter, J. J. Thomson demonstrated the existence of negatively electrified corpuscles much smaller than the least of the so-called atoms, and pictured the atom as made up of such corpuscles, they were at once identified with the electrons, or isolated electric units, of Lorentz and Larmor.

Moreover, on the electric theory which pictures matter as made up of electrons in orbital motion, it was difficult to see why atoms should be invariably permanent and stable systems. Acceleration of the electrons would cause radiation and loss of energy, and systems stable while in rapid motion should sometimes break up as the motion became slower. Hence, when the phenomena of radio-activity forced the experimental physicist to face the possibility of atomic disintegration, a difficulty in the path of the electronic theory of the mathematician was removed. The occasional instability which he had foreseen as a consequence of his theory was found to be indicated as a more direct consequence of experiment.

Conceiving the atom as composed of a number of negative corpuscles or electrons, placed within a sphere of positive electrification in order to secure an inward force, Thomson has deduced many of the observed periodic properties of the chemical elements with regard to their valency and to the nature of their spectra. Under the influence of their mutual repulsion, and of the central attraction of the hypothetical positive sphere, the corpuscles assume positions of equilibrium similar to those shown by a number of little vertical magnets, floated on water by corks, and drawn together by a large magnetic pole placed above them. As the number of magnets is increased, different patterns are formed, and patterns somewhat similar to each other will recur with stated numbers, thus recalling to mind the recurrence of similar chemical elements at regular intervals in Mendeleeff's periodic table, in which the elements are arranged in ascending order of their atomic weights. The nature or meaning of the hypothetical sphere of positive electrification remains to be elucidated; in fact, the nature of positive electricity may be considered as the most pressing question of electrical science.

A moving electrified sphere carries with it the tubes of electric force represented in Figure 97 on page 205. Moving tubes of force imply a magnetic field proportional to their number and velocity, and hence to set such a sphere in motion requires the expenditure of the work necessary to establish the energy of the magnetic field. When once established, the momentum of the moving tubes, studied on page 210, will tend to keep them in motion; thus, owing to its electric charge, the effective inertia of the sphere is increased.

Let us apply this result to the case of a moving corpuscle. Theory shows that, for moderate speeds, the electric inertia outside a small sphere of radius  $r$  surrounding the electrified particle is given by  $2e^2/3r$ , where  $e$  is the charge on the particle. But, as the velocity of light is approached, this electric mass grows very rapidly. Now, in the  $\beta$  rays of radium, we may examine negatively electrified particles moving with different velocities, some of which approach that of light. By measuring photographically the magnetic and electric deflections of these  $\beta$  particles, Kaufmann has shown

that the ratio  $m/e$  of the mass to the charge of these particles increases as they near the velocity of light.

On the electron theory, matter is an electric manifestation, and the mass of a body must be explicable as electric inertia. On the assumption that the whole of the mass is electrical, Thomson has calculated the ratio of the mass of a corpuscle moving with different speeds to the mass of a slowly moving corpuscle, and compared these values with the results of Kaufmann's experiments.

Velocity of Corpuscle in Centimetres per second	Ratio of Mass to the Mass of a slowly moving Corpuscle	
	Calculated	Observed
$2.36 \times 10^{10}$	1.65	1.5
$2.48 \times 10^{10}$	1.83	1.66
$2.59 \times 10^{10}$	2.04	2.0
$2.72 \times 10^{10}$	2.43	2.42
$2.85 \times 10^{10}$	3.09	3.1

In this remarkable manner has it been possible to obtain experimental confirmation of the theory that mass is an electrical or æthereal phenomenon.

We have now explained, or explained away, the most fundamental dynamical property of matter, and still the mind is unsatisfied. It asks at once: What is the nature of this electric inertia into which mass has been resolved?

As we have seen, in § 73, it is possible to represent the inertia of a magnetic field as due to electric tubes of force in motion, dragging with them some of the luminiferous æther. In this way electric inertia is in its turn "explained" as "mechanical" inertia—of the hypothetical substance invented to enable our minds to form a rational picture of other physical phenomena.

No doubt, in a certain sense, simplification is thus attained. All natural phenomena are referred to the properties of the æther, and a complete theory of the æther would give us a complete account of the physical universe. Nevertheless the mystery

is but changed; it is not dissipated. We may have explained matter in terms of æther; how are we to explain æther?

It is not without significance that a book on a branch of physical science closes most naturally with an unanswered question.

- JAHN, reversible cells, 244
- JENKIN, STEWART and MAXWELL, absolute unit of resistance, 183
- JOULE, process of magnetization, 87; thermal equivalent of current, 133

'Joule,' value of unit, 188

KAUFMANN, deflection of  $\beta$  particles, 326

KELVIN, Lord, electrical images, 27; guard ring device, 38; quadrant electrometer, 44; galvanometer, 94; thermo-electric circuit, 135; absolute measurement of current, 179; ratio of units, 196; electromotive force of voltaic cell, 245

KIRCHHOFF, principles of current flow, 117; absolute resistance of wire, 183

KOHLRAUSCH, specific conductivity of solutions, 228, 231; mobility of ions, 235

KOHLRAUSCH and HOLBORN, electrochemical equivalents, 225

KOHLRAUSCH and WEBER, ratio of units, 195

LAPLACE, law of inverse squares, 17

LARMOR, radiation pressure, 212; electrons, 325

LATIMER CLARK, standard cell, 130

LEBEDEFF, radiation pressure, 212

LE BLANC, electromotive force of polarization, 218

LENARD, mass of gaseous ions, 300

LENZ, law of least action, 148

LE ROUX, absence of Thomson effect in lead, 140

Leyden Jar, invention of, 3; Franklin's experiments with, 5

Lightning, nature of, 6, 114

Lines of force, 50 et seq.

LIPPMANN, capillary electrometer, 257, 260

LODGE, Sir OLIVER, coherer for wireless telegraphy, 203; measurement of ionic velocity, 238

LORENZ, determination of ohm, 185

LORENTZ, electrons, 325

Magnetic force, definition of, 74; laws of, 77; in magnetic shell, 97; inside a solenoid, 100; due to a current, 101; due to movement of electrostatic charges, 212

Magnetic induction, 73, 80

Magnetic permeability, 85

Magnetic potential, 67, 98

Magnetic saturation, 82, 83

Magnetic shell, 97

Magnetic susceptibility, 74

Magnetism, early history of, 60; principal phenomena of, 61; terrestrial, 68; effect of temperature on, 74; theories of, 86

Magnetometer, 66

Magnets, permanent and occasional, 62; interaction of, 66

MARCONI, electromagnetic detector, 204  
MAXWELL, J. CLERK, law of inverse squares, 20; electric displacement, 55, 56; electromagnetic waves 56; energy of electromagnetic system, 190; ratio of units, 196; radiation pressure, 212

MAXWELL, JENKIN and STEWART, absolute unit of resistance, 183

MENDELEEFF, periodic law, 326

MICHELL, Rev. JOHN, torsion balance, 13

Migration of ions, 232

Mobility, ionic, 235, 291

Momentum in electromagnetic field, 210

Motors, 165

MUSCHENBROECH, Leyden Jar, 3

Negative glow, 276

NERNST, electromotive force of concentration cells, 250, 251

NEUMANN, laws of induction, 149; single potential differences, 261, 262

NEVILLE and HEXCOCK, points of recalcence, 128

NEWTON, Sir ISAAC, inverse square law, 16, 49; corpuscles, 300

NICHOLSON and CARLISLE, electrolytic decomposition of water, 215

NORMAN, ROBERT, rediscovery of the dip, 61

Nuclei, condensation, 295

OBERBECK, electromotive force of polarization, 218

OERSTED, magnetic effect of electric current, 93

OHM, current and electromotive force, 113

'Ohm,' value of unit, 187

Optical indices and dielectric constants, 197

ORME-MASSON, ionic velocities, 239

Oscillations, electric, 162

Oscillator, electric, 199

Oscillograph, 158

Osmotic pressure, 247, 251, 267

OSTWALD, electromotive force of concentration cell, 251; dilution law, 271

PASCHEN, sparking potential, 275

PELTIER, heat effect at circuit junctions, 134

Peltier effect, 255

Periodic law, 326

Permeability, magnetic, 85

PERRY and AYRTON, ratio of units, 196; contact effect, 254

Pitchblende, radium found in, 307

Platinum thermometer, 124

- Polarization, dielectric, 55, 193; in electrolysis, 218  
 Polonium, discovery of, 308  
 Potential differences, 256, 261

**Conduction of Electricity through Gases.** By J. J. THOMSON, D.Sc., LL.D., Ph.D., F.R.S., Fellow of Trinity College and Cavendish Professor of Experimental Physics. Demy 8vo. viii+568 pp. 16s.

## CONTENTS.

<p>I. Electrical Conductivity of Gases in a normal state.</p> <p>II. Properties of a Gas when in the conducting state.</p> <p>III. Mathematical Theory of the Conduction of Electricity through a Gas containing Ions.</p> <p>IV. Effect produced by a Magnetic Field on the Motion of the Ions.</p> <p>V. Determination of the Ratio of the Charge to the Mass of an Ion.</p> <p>VI. Determination of the Charge carried by the Negative Ion.</p> <p>VII. On some Physical Properties of Gaseous Ions.</p> <p>VIII. Ionisation by Incandescent Solids.</p>	<p>IX. Ionisation in Gases from Flames.</p> <p>X. Ionisation by Light. Photo-Electric Effects.</p> <p>XI. Ionisation by Röntgen Rays.</p> <p>XII. Becquerel Rays.</p> <p>XIII. Spark Discharge.</p> <p>XIV. The Electric Arc.</p> <p>XV. Discharge through Gases at Low Pressures.</p> <p>XVI. Theory of the Discharge through Vacuum Tubes.</p> <p>XVII. Cathode Rays.</p> <p>XVIII. Röntgen Rays.</p> <p>XIX. Properties of Moving Electrified Bodies.</p> <p>Supplementary Notes.</p> <p>Index.</p>
---	--

*Times*.—"It is difficult to think of a single branch of the physical sciences in which these advances are not of fundamental importance. The physicist sees the relations between electricity and matter laid bare in a manner hardly hoped for hitherto....The workers in the field of Science are to-day reaping an unparalleled harvest, and we may congratulate ourselves that in this field at least we more than hold our own among the nations of the world."

**A Treatise on the Theory of Solution, including the Phenomena of Electrolysis.** By WILLIAM CECIL DAMPIER WHETHAM, M.A., F.R.S., Fellow of Trinity College. Demy 8vo. x+488 pp. 10s. net.

*Athenæum*.—"The choice and arrangement of the matter included are alike excellent....Mr Whetham's book is probably the most complete and satisfactory treatise on the subject in any language and as such is sure to enjoy a wide popularity."

*Nature*.—"The treatment throughout is characterised by great clearness, especially in the physical and mathematical portions, so that the volume may be warmly recommended to students of chemistry."

# CAMBRIDGE PHYSICAL SERIES.

## CONTENTS OF MR WHETHAM'S 'SOLUTION AND ELECTROLYSIS.'

I.	Thermodynamics.	X.	Galvanic Cells.
II.	The Phase Rule.	XI.	Contact Electricity and Polarization.
III.	The Phase Rule. Two Components. Solutions.	XII.	The Theory of Electrolytic Dissociation.
IV.	Solubility.	XIII.	Diffusion in Solutions.
V.	Osmotic Pressure.	XIV.	Solutions of Colloids.
VI.	Vapour Pressures and Freezing Points.		Additions.
VII.	Theories of Solution.		Table of Electro-chemical Properties of Aqueous Solutions.
VIII.	Electrolysis.		
IX.	Conductivity of Electrolytes.		

**Electricity and Magnetism: an Elementary Text-book,**  
Theoretical and Practical. By R. T. GLAZEBROOK, M.A., F.R.S.,  
Director of the National Physical Laboratory and Fellow of Trinity  
College, Cambridge. Crown 8vo. Cloth. 1—440 pp. 7s. 6d.

*Athenæum*.—"If the nature of the book be taken into consideration, it will be found unusually free from the influence of the examination spirit. The writing is bright and interesting, and will stimulate a desire, we think, for further study."

*Guardian*.—"Every schoolmaster and teacher who has under consideration the selection of a text-book for his better students should most certainly look into this book. The information is everywhere absolutely sound and reliable."

**PREFACE.** Some words are perhaps necessary to explain the publication of another book dealing with Elementary Electricity. A considerable portion of the present work has been in type for a long time; it was used originally as a part of the practical work in Physics for Medical Students at the Cavendish Laboratory in connexion with my lectures, and was expanded by Mr Wilberforce and Mr Fitzpatrick in one of their Laboratory Note-books of Practical Physics.

When I ceased to deliver the first year course I was asked to print my lectures for the use, primarily, of the Students attending the practical classes; the lectures on Mechanics, Heat and Light have been in type for some years. Other claims on my time have prevented the issue of the present volume until now, when it appears in response to the promise made several years ago.

Meanwhile the subject has changed; but while this is the case the elementary laws and measurements on which the science is based remain unaltered, and I trust the book may be found of service to others besides my successors at the Cavendish Laboratory.

The book is to be used in the same way as its predecessors. The apparatus for most of the Experiments is of a simple character and can be supplied at no great expense in considerable quantities.

Thus the Experiments should all, as far as possible, be carried out by the members of the class, the teacher should base his reasoning on the results actually obtained by his pupils. Ten or twelve years ago this method was far from common; the importance to a School of a Physical Laboratory is now more generally recognized; it is with the hope that the book may be of value to those who are endeavouring to put the method in practice that it is issued now.

---

**Heat and Light.** An Elementary Text-book, Theoretical and Practical, for Colleges and Schools. By R. T. GLAZEBROOK, M.A. Crown 8vo. 5s.

Also in separate volumes :

**Heat.** 230 pp. 3s.

**Light.** 213 pp. 3s.

**Mechanics and Hydrostatics.** An Elementary Text-book, Theoretical and Practical, for Colleges and Schools. By R. T. GLAZEBROOK, M.A. Crown 8vo. 8s. 6d.

Also in separate volumes :

**Part I. Dynamics.** 256 pp. 4s.

**Part II. Statics.** 182 pp. 3s

**Part III. Hydrostatics.** 216 pp. 3s.

## EXTRACTS FROM PRESS NOTICES.

"Schools and Colleges will certainly benefit by adopting this book for their students." *Nature*.

"Mr Glazebrook's volumes on Heat and Light deal with these subjects from the experimental side and it is difficult to admire sufficiently the ingenuity and simplicity of many of the experiments without losing sight of the skill and judgment with which they are arranged." *Saturday Review*.

"The books almost cover the advanced stages of the South Kensington prospectus and their use can certainly be recommended to all who wish to study these subjects with intelligence and thoroughness." *Schoolmaster*.

"Mr Glazebrook's great practical experience has enabled him to treat the experimental aspect of the book with unusual power and it is in this that the great value of the book as compared with most of the ordinary manuals consists." *Educational Review*.

"The book is very simply and concisely written, is clear and methodic in arrangement....We recommend the book to the attention of all students and teachers of this branch of physical science." *Educational News*.

"We wish Mr Glazebrook every success on the extension of his practical system to all the Colleges and Schools of the country. It is the only way in which the interest of the student can be awakened and the study of the subject made popular and real." *Technical World*.

"It will be especially appreciated by teachers who possess the necessary apparatus for experimental illustrations." *Athenaeum*.

"Text-books on this subject are generally too simple or too elaborate for a conception of elementary mechanical principles. This book cannot fail to recommend itself therefore for a first course preliminary to the study of physical science. No other book presents in the same space with the same clearness and exactness so large a range of mechanical principles." *Physical Review*.

"Marked ability has been shewn in the development of the subject of Statics in the present volume....The collected examples for students' exercises are excellent." *Glasgow Herald*.

# CAMBRIDGE PHYSICAL SERIES.

General Editors: F. H. NEVILLE, M.A., F.R.S. and  
W. C. D. WHETHAM, M.A., F.R.S.

**Mechanics.** By JOHN COX, M.A., F.R.S.C., Macdonald  
Professor of Experimental Physics in McGill University, Montreal.  
Demy 8vo. pp. xiv + 332. 9s. Net.

*Athenæum*.—"It may reasonably be hoped that this endeavour to bridge over the gulf which has hitherto separated theory from practice in respect of the principles of mechanics, by showing their intimate connexion, and to present the subject in a more living and attractive form, by drawing attention to the gradual stages and methods by which the early investigators discovered the laws which govern the science, will meet with the success which it deserves."

**The Study of Chemical Composition.** An Account of  
its Method and Historical Development, with illustrative quotations.  
By IDA FREUND, Staff Lecturer and Associate of Newnham College.  
Demy 8vo. xvi + 650 pp. 18s. Net.

*Saturday Review*.—"Written from a broad, philosophical standpoint, we know of no book more suited for the student of chemistry who has attained a sound general knowledge of the science, and is now ready to appreciate a critical discussion of the methods by which the results he has learnt have been built up, thereby fitting himself for the real world of investigation on his own account."

**A Treatise on the Theory of Alternating Currents.**  
By ALEXANDER RUSSELL, M.A., M.I.E.E.  
Vol. I. Demy 8vo. pp. 408. 12s. Net.  
Vol. II. In the Press.

*Scotsman*.—"The volume is not only rich in its own substantive teaching, but well supplied with references to the more remote authorities upon its subject. It opens an important and valuable contribution to the theoretical literature of electrical engineering."

**Radio-activity.** By E. RUTHERFORD, D.Sc., F.R.S., F.R.S.C.,  
Macdonald Professor of Physics, McGill University, Montreal. Demy  
8vo. pp. x + 400. 10s. 6d. Net.

*Athenæum*.—"English students have had to wait till now for any connected and detailed account of this new branch of physics from the pen of one who has a first hand knowledge of it."

*Nature*.—"The arrangement of the matter and its treatment are throughout admirable."

**The Theory of Experimental Electricity.** By  
W. C. D. WHETHAM, M.A., F.R.S., Fellow of Trinity College.  
Demy 8vo. 8s. Net.
